SUSTAINING LIFE IN EVEN THE MOST CHALLENGING ENVIRONMENT.

THE TENTH ANNIVERSARY OF THE MONOSTRUT™ HEART VALVE MARKS A SIGNIFICANT MILESTONE IN THE CLINICAL APPLICATION OF ADVANCED TECHNOLOGY. AS WE MOVE INTO OUR SECOND DECADE OF MONOSTRUT™ IMPLANT EXPERIENCE, WE REMAIN COMMITTED TO PROVIDING YOU AND YOUR PATIENTS WITH A VALVE WHOSE OVERALL PERFORMANCE IS UNMATCHED.

THE COMMITMENT SHOWS. BECAUSE IN IMPLANT AFTER IMPLANT, THE MONOSTRUT™ HAS DEMONSTRATED FLAWLESS MECHANICAL PERFORMANCE, EXCELLENT HEMODYNAMIC RESULTS AND THE *VIRTUAL ELIMINATION OF THROMBOSIS*.

ONLY THE MONOSTRUT™ INCORPORATES AN INTEGRATED, ONE-PIECE DESIGN WITH A FREE-FLOATING DISC. CONTACT BETWEEN THE DISC AND VALVE FLANGE IS ELIMINATED DURING OPENING, PREVENTING STASIS.

EXPERIENCE TRUE COMMITMENT. CHOOSE THE MONOSTRUT™ HEART VALVE. IT'S THE NATURAL CHOICE WHEN NATURE IS UNABLE TO HELP ITSELF.

NOT AVAILABLE IN THE U.S.A.

ELITE®

Last year we introduced the 38-gram ELITE® DDD/R pacemaker.

Physicians responded by making ELITE® the world's most widely prescribed dual chamber pacemaker.

Today, the ELITE® technology has been enhanced, and it's now available in a pacemaker that is 30% smaller, the 26-gram ELITE II™.

ELITE II™ enhancements include

- ☐ separately programmable upper rates (sinus or sensor) for managing brady-tachy patients,

THE WORLD'S MOST WIDELY PRESCRIBED DUAL CHAMBER TECHNOLOGY

- ☐ the ability to do electrophysiologic studies¹ for premature electrical stimulation or burst pacing, and
- ☐ Marker Channel™ Diagrams¹ to aid interpretation of cardiac activity and pacemaker operation.

Plus, **ELITE II™** offers

- ☐ a dedicated bipolar model for use with implantable cardioverter-defibrillators,
- ☐ a proven atrial sense amplifier for superior atrial sensing, and

P E T I T E E L I T E[®]

- 19 pacing modes for therapeutic flexibility.

Coupled with our easy-to-use programmers (portable 9710A or desktop 9760) and our low-threshold, steroid eluting CapSure[®] SP leads, the ELITE II[™] pacing system is *simply more powerful*.

Of course, experience counts as well. The ELITE II[™] pacemaker is Medtronic's eighth-generation rate responsive device. Our patented sensor technology now has been implanted in nearly 300,000 patients worldwide.²

**NOW
ENHANCED IN
A PACEMAKER
THAT'S 30%
SMALLER**

And with recent studies showing the benefits of atrial-based pacing in patients with sick sinus syndrome (i.e., increased survival, reduced incidence of atrial fibrillation and congestive heart failure),^{3,4} it's no surprise that you and your colleagues are now prescribing dual chamber pacemakers for 47% of your pacemaker patients, compared to only 25% five years ago.⁵

Once you try the new ELITE II[™], we think you'll want to consider it for all your pacing patients.

SIMPLY MORE POWERFUL.

Medtronic 

SIMPLY MORE POWERFUL.

References: 1. Currently not available. Future software will allow this capability. See your Medtronic representative for availability. 2. Medtronic data on file. 3. Rosenqvist M, Brandt J, Schüller H, et al. Long-term pacing in sinus node disease: effects of stimulation mode on cardiovascular morbidity and mortality. *Am Heart J.* 1988;116(1 pt 1):16-22. 4. Santini M, Alexidou G, Ansalone G, et al. Relation of prognosis in sick sinus syndrome to age, conduction defects, and modes of permanent cardiac pacing. *Am J Cardiol.* 1990;65(11):729-735. 5. Industry Marketing Survey data.

INTENDED USE: The ELITE II™ dual chamber pacemaker is for therapeutic management of heart rate disorders when restoration of AV synchrony or the need for rate response is indicated. The DDDR, DDIR, and DVIR pacing modes are for persistent sinus brady, uncontrollable brady-tachy syndrome, and sinus pause/arrest. The AAIR mode is for sinus node dysfunction and intact AV conduction. The VVIR mode is for chronic atrial flutter or fibrillation with a slow ventricular response, certain atrial or ventricular arrhythmias, or situations where it is desirable to disable the atrial channel (e.g., inexcitable atrium). See product labeling for a detailed list of intended uses for the 19 pacing modes available.

CONTRAINDICATIONS: In the presence of chronic atrial flutter or fibrillation, the DDDR, DDD, DDIR, and DDI modes may be contraindicated and atrial pacing in the DVIR and DVI modes is ineffective. The AAIR, AAJ, AAT, AOCR, and AOO modes are contraindicated in the presence of AV conduction disturbances. The asynchronous pacing modes are contraindicated if competition between paced and intrinsic rhythms is likely. Do not use steroid eluting leads in patients for whom a single dose of 1.0 mg dexamethasone sodium phosphate may be contraindicated.

WARNINGS: Do not use diathermy over the pacemaker or defibrillation paddles within 12 cm of the pacemaker; damage to the pacemaker's electronic components may result. Do not use electrosurgical units within 15 cm of implanted pacing systems; this may introduce fibrillatory currents into the heart. Confirm pacemaker operation after diathermy, defibrillation, or electrosurgical procedures.

PRECAUTIONS: Electrical discharges from implantable cardioverter/defibrillators or external cardioversion may reset all models to the VVI mode and a bipolar ELITE II™ Model 7086 to unipolar pacing and sensing. If Model 7086 is implanted with IS-1 unipolar leads, polarity must remain unipolar to maintain output and sensing capability. Proper operation may also be affected by interference from certain electrical equipment. Any pacing system may fail due to random component or battery failures, lead-related problems, or eventual cell depletion.

SIDE EFFECTS: Possible side effects include, but may not be limited to, body rejection phenomena, muscle and nerve stimulation, infection, erosion of pacing system through skin, thrombosis related to transvenous leads, embolism, and cardiac tamponade.

See the technical manual for more detailed information.

THE CLEVELAND CLINIC FOUNDATION René G. Favaloro, MD International Fellowship in Cardiac Surgery

The Department of Thoracic and Cardiovascular Surgery is proud to announce the René G. Favaloro, MD, International Fellowship in Cardiac Surgery. This one-year fellowship has been created for trainees in cardiac surgery outside the United States who exhibit outstanding characteristics in clinical skills and scholarly ability.

The Cleveland Clinic Foundation's Department of Thoracic and Cardiovascular Surgery performs 3,000 open heart operations annually with an increasing proportion of either complex procedures or reoperations. Active sections exist in all facets of adult cardiac surgery including: reparative valvular procedures, electrophysiological surgery, heart transplantation, myoplasty and circulatory support.

Inquiries should be addressed to:

INTRODUCING

The LaserSonics Advantage For Thoracoscopy

***Precision...
Preservation...
Maneuverability...
Coagulation...
Safety...***

You know what you need for operative thoracoscopy. But what you've been using can't always deliver. LaserSonics Nd:YAG systems fill the gap ...with solutions that provide coagulative sealing, hemostatic resection and maximum preservation of parenchyma.

Now, discover for yourself how LaserSonics' Nd:YAG technology can enhance the utility of video-assisted thoracic surgery. Send for a FREE video demonstration, stop by our booth at the upcoming meetings, or look for us at your next course.

Heraeus LaserSonics, Inc.

LaserSonics Nd:YAG Surgical Laser Technology For Enhanced Thoracoscopy

Heraeus LaserSonics' unique configuration of Nd:YAG laser technology provides maximum preservation of healthy tissue, regardless of nodule size, depth or location. Coupled with our versatile line of quartz fiberoptic accessories, the LUXUS® Nd:YAG laser system can actually provide several different tissue effects for hemostatic resection, deep coagulative sealing, or precise excision without electrical stimulation. Innovative instrumentation improves pleural and pulmonary accessibility, while the ClearView™ Environmental Balancing System ensures maximum visualization of the operative site.

HEMOSTASIS.

The easy way,
any way,
every way,
the versatile spray.

Accesses hard-to-reach sites
In neurosurgery, THROMBOGEN Thrombin provides hemostasis in hard-to-reach sites, such as deep tumor beds.

Sprays at any angle
In cardiovascular surgery, control oozing under the sternum by spraying THROMBOGEN Thrombin upside down.

Covers broad areas evenly
In burn surgery, an even and consistent spray of THROMBOGEN Thrombin controls bleeding of broad areas, such as donor sites.

THROMBOGEN*

Topical Thrombin, USP

Johnson & Johnson
MEDICAL INC.

*TRADEMARK © J.J.M. INC. 1991

For further product information, call 1-800-433-5009.

Please see following page for brief summary of Prescribing Information.

Thrombin, Topical USP THROMBOGEN* (Bovine origin)

Before prescribing, please see full prescribing information. A Brief Summary follows: Thrombin, Topical USP THROMBOGEN* must not be injected! Apply on the surface of bleeding tissue as a solution or powder.

INDICATIONS AND USAGE: THROMBOGEN Thrombin is indicated as an aid in hemostasis wherever oozing blood from capillaries and small venules is accessible.

In various types of surgery, solutions of THROMBOGEN Thrombin may be used in conjunction with Absorbable Gelatin Sponge, USP for hemostasis.

CONTRAINDICATIONS: THROMBOGEN Thrombin is contraindicated in persons known to be sensitive to any of its components and/or to material of bovine origin.

WARNING: Because of its action in the clotting mechanism, THROMBOGEN Thrombin must not be injected or otherwise allowed to enter large blood vessels. Extensive intravascular clotting and even death may result. THROMBOGEN Thrombin is an antigenic substance and has caused sensitivity and allergic reactions when injected into animals.

PRECAUTIONS: General: Consult the Absorbable Gelatin Sponge, USP product labeling for complete information for use prior to utilizing the thrombin-saturated-sponge procedure.

Pregnancy-teratogenic effects: Pregnancy Category C. Animal reproduction studies have not been conducted with Thrombin, Topical USP (Bovine origin). It is also not known whether Thrombin, Topical USP (Bovine origin) can cause fetal harm when administered to a pregnant woman or can affect reproduction capacity. Thrombin, Topical USP (Bovine origin) should be given to a pregnant woman only if clearly indicated.

Pediatric Use: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS: Allergic reactions may be encountered in persons known to be sensitive to bovine materials.

DOSAGE AND ADMINISTRATION: General: Solutions of THROMBOGEN Thrombin may be prepared in sterile distilled water or isotonic saline. The intended use determines the strength of the solution to prepare. For general use in plastic surgery, dental extractions, skin grafting, neurosurgery, etc., solutions containing approximately 100 units per ml are frequently used. For this, 10 ml of diluent added to the 1,000 unit package is suitable. When bleeding is profuse, as from cut surfaces of liver and spleen, concentrations as high as 1,000 to 2,000 units per ml may be required. Intermediate strengths to suit the needs of the case may be prepared by selecting the proper strength package and dissolving the contents in an appropriate volume of diluent. In many situations, it may be advantageous to use THROMBOGEN Thrombin in dry form on oozing surfaces.

CAUTION: Solutions should be used immediately upon reconstitution. However, the solution may be refrigerated at 2-8°C for up to three hours. The following techniques are suggested for the topical application of THROMBOGEN Thrombin.

1. The recipient surface should be sponged (not wiped) free of blood before THROMBOGEN Thrombin is applied.
2. A spray may be used or the surface may be flooded using a sterile syringe and small gauge needle. The most effective hemostasis results when the THROMBOGEN Thrombin mixes freely with the blood as soon as it reaches the surface.
3. In instances where THROMBOGEN Thrombin in dry form is needed, the vial is opened by removing the metal ring by flipping up the plastic cap and tearing counterclockwise. The rubber-diaphragm cap may be easily removed and the dried THROMBOGEN Thrombin is then broken up into a powder by means of a sterile glass rod or other suitable sterile instrument.
4. Sponging of treated surfaces should be avoided in order that the clot remain securely in place. THROMBOGEN Thrombin may be used in conjunction with Absorbable Gelatin Sponge, USP as follows:
 1. Prepare THROMBOGEN Thrombin solution of the desired strength.
 2. Immerse sponge strips of the desired size in the THROMBOGEN Thrombin solution. Knead the sponge strips vigorously with moistened gloved fingers to remove trapped air, thereby facilitating saturation of the sponge.
 3. Apply saturated sponge to bleeding area. Hold in place for 10 to 15 seconds with a pledget of cotton or a small gauze sponge.

THROMBOGEN Spray Kit: The THROMBOGEN Spray Kit contains one sterile vial of THROMBOGEN Thrombin, one sterile vial of isotonic saline diluent, one sterile disposable syringe and one sterile syringe spray tip. The kit may be used as follows:

1. Remove the Tyvek® blister lid from the outermost tray by pulling up at the indicated corner. The sterile inner tray can then be lifted out or introduced into the sterile field.
2. Remove the Tyvek® blister lid from the inner tray to expose the sterile contents.
3. Using the sterile syringe equipped with the needle, draw the desired amount of saline diluent from the vial into the syringe.
4. Inject the saline diluent into the THROMBOGEN Thrombin vial from the syringe to reconstitute the THROMBOGEN Thrombin powder.
5. When the THROMBOGEN Thrombin is completely dissolved, draw the THROMBOGEN Thrombin solution into the syringe.
6. Remove and discard the needle, affix spray tip by pushing down and turning clockwise until the spray tip locks in place.
7. Depress the syringe plunger in a normal fashion to dispense the THROMBOGEN Thrombin solution through the tip in a fine spray.
8. Alternatively, to facilitate using the THROMBOGEN Thrombin with an Absorbable Gelatin Sponge, USP the THROMBOGEN Thrombin solution may be dispensed directly from the syringe into a sterile container vs. attaching the spray tip. When THROMBOGEN Thrombin is needed in the dry form, the vial is opened and the dried THROMBOGEN Thrombin pellet should be broken up into a powder with a sterile glass rod or other suitable instrument.

Caution: Federal law prohibits dispensing without a prescription.

THROMBOGEN Thrombin is manufactured by GenTrac, Inc. Middleton, WI 53562.

THROMBOGEN Thrombin is a trademark of Johnson & Johnson Medical, Inc. †Trademark of DuPont.

Store at normal controlled room temperature, except 1000 unit vial of THROMBOGEN Thrombin, which must be stored between 2°-8°C (36°-46°F).

Years of Combined Experience

For over 20 years, our
Medtronic Hancock® tissue
valve has established a history
of solid clinical experience.
A history longer than any
other commercially available
porcine bioprosthesis.

For 15 years the Medtronic
Hall™ mechanical valve has
had unsurpassed durability.
Its hemodynamic performance
rivals that of any mechanical
valve – with superior
performance in the small
aortic annulus.¹

Add our experience to yours.

Cardiac Surgery

Second Edition

By **John W. Kirklin, MD** and **Brian G. Barratt-Boyes, KBE MB ChM**
With the collaboration of **Richard A. Jonas, MD**, **Nicholas T. Kouchoukos, MD**,
and **Eugene H. Blackstone, MD**

Based on the vast personal experience of two of the world's preeminent specialists in cardiac surgery — supplemented by that of renowned surgeons, Drs. Jonas and Kouchoukos — the **Second Edition** of this definitive text provides thorough knowledge and practical applications of the state of the art, with comprehensive coverage of: ischemic, valvular, and congenital heart diseases; cardiac tumors; constrictive pericarditis; thoracic aortic surgery; cardiac transplantation, and much more. This exhaustively revised **Second Edition** also features:

- 90% new material, with new information on natural history and diagnosis, data analysis, and new operations
- Updated information in **every chapter** on indications and outcomes for all types of surgery
- Superb, highly detailed artwork, including over 500 new illustrations

Use our convenient toll-free number to reserve your copy today!

"This book will serve well and long as an addition to, if not almost a replacement for, the libraries of cardiac surgeons...practitioners of every specialty involving the treatment of patients with heart disease should read this unique book with pleasure and profit."

— **The New England Journal of Medicine**

DLP Introduces the New Retrograde Coronary Sinus Perfusion Cannula

DLP again extends the choice of cannula options to meet the needs of a wider range of physicians. With its 12 1/2" long body, this cannula provides the stability some physicians prefer while still resisting troublesome kinking. The Auto-Inflating RSCP cannula features a unique, bullet nose tip with three channels, for cardioplegia outflow. The channels significantly reduce jetting and additionally protect the pressure monitoring port.

THE TRU-TOUCH™ STYLET HANDLE

The RCSP cannula features DLP's newest innovation, the Tru-Touch stylet handle. Unlike other stylets that are patterned after the laparoscope, this handle gives the physician true tactile control. The Tru-Touch stylet allows the physician to use natural hand movement for fingertip controlled cannula placement.

ADDITIONAL FEATURES

- Ten, small diameter, flow-through ports reduce the possibility of inadvertent stylet caused balloon damage
- Flow-through balloon design provides better distention at lower pressures
- Integral stopcock on pressure monitoring line
- Female luer lock connector

CATALOG CODES

Auto-Inflating RSCP Cannula with Tru-Touch Handle

Think Of It As An Air Bag For Each Vessel.

Our Retractable-O-Tape® vascular loop gently and safely stabilizes an anastomotic site. Each loop is made of hollow, silicone tubing sealed at both ends to hold air. During

retraction and occlusion, this flexible air cushion works like an air bag to minimize trauma to vessels and surrounding tissue. With pressure, Retractable-O-Tape flattens out enough to properly occlude or retract the vessel, but not so much that it creates flat edges that can cause harm.

The Retractable-O-Tape vascular loop also improves visualization in the surgical field. For example, during warm continuous blood cardioplegia, Retractable-O-Tape can provide a dry and clear anastomotic site. Consequently, the Retractable-O-Tape vascular loop is not only easy on your patient, but also easy on you.

The patented needle passes easily around the vessel without dissecting surrounding tissue.

Retractable-O-Tape comes in needle and non-needle versions, and are radiopaque and highly visible in the surgical field. The needle versions come in a thin wall, 18 gauge, 12 inch length, while the non-needle versions cover a range of lengths and gauges. No matter what the procedure, Retractable-O-Tape can make it go a little smoother. Just as it has throughout the world for the past 15 years.

To receive your free samples, call **1-800-627-0226 Ext. 266** or fax your request to us at 1-214-404-0275 *Attention: Customer Service*. We'll send you a non-sterile loop to examine and a sterile one to use in your next surgery.

Retractable-O-Tape is available in a variety of gauges and lengths to meet your needs.

A cushion of air protects the vessel during occlusion and retraction.

*Announcing research opportunities
in blood conservation*

**Two \$25,000 grants
supported by Miles Inc.**

1. Clinical research in blood conservation in thoracic surgery: \$25,000
2. Clinical research in blood conservation in cardiovascular anesthesia: \$25,000

Grant Information

- ☐ Both grants are provided by Miles Inc., Pharmaceutical Division; selection is by an independent, highly-qualified selection committee
- ☐ Eligibility is limited to physicians who have been in academic staff positions for no more than four years
- ☐ No more than 25% of the grant is to be used by the physicians' institution for indirect costs
- ☐ Clinical research resulting from the grant will be submitted for publication by the physician

Grant deadline:
March 15, 1993

Grant Announcement by
May 15, 1993

To request application:
Call Bruce Leeb & Company
(201) 612-8919

Grant Selection

- ☐ The grant selection committee is chaired by

Michael N. D'Ambra, M.D.
Director, Cardiac Anesthesia Group
Massachusetts General Hospital
Boston, Massachusetts

- ☐ Dr. D'Ambra is joined in the selection of the grantees by

Leonard L. Firestone, M.D.
Chief of Cardiac Anesthesia
University of Pittsburgh
Pittsburgh, Pennsylvania

Christina T. Mora, M.D.
Assistant Professor of Anesthesiology
Emory University School of Medicine
Atlanta, Georgia

Hartzell V. Schaff, M.D.

THE ANNALS OF THORACIC SURGERY INFORMATION FOR AUTHORS

Thomas B. Ferguson, MD
Editor, *The Annals of Thoracic Surgery*
3108 Queeny Tower
Barnes Hospital Plaza
St. Louis, MO 63110-1041
(314) 361-6084 FAX: (314) 367-0585

The Annals of Thoracic Surgery publishes original papers on topics in thoracic and cardiovascular surgery. Also featured are case reports, "how to do it" articles, classics in thoracic surgery, collective and current reviews, correspondence, and book reviews. All manuscripts, correspondence, and editorial business should be sent to the above address. Guidelines for collective and current reviews are available on request.

If a manuscript is accepted for publication, certain conditions must be agreed to by all authors. These include statements regarding conflict of interest, scientific responsibility, exclusive publication, and assignment of copyright. Elsevier Science Publishing Co, Inc, will maintain records of copyright for The Society. No part of the published material may be reproduced elsewhere without written permission from the publisher.

Because of escalating postage costs, manuscripts and illustrations will not routinely be returned to the authors. The editorial office will be responsible for proper disposal of the manuscripts so that confidentiality is preserved. Manuscripts and illustrations will be returned only if requested and a self-addressed stamped (US postage) envelope provided.

Checklist

The following checklist is provided for the author's convenience. Please utilize this list to make certain the manuscript is complete when submitted. Incomplete manuscripts cannot be accepted for editorial review.

General

- ☐ Submit original and *two* duplicate manuscripts (including three clearly separated and labeled sets of illustrations). Retain a fourth complete set as insurance against loss in the mail.
- ☐ Type manuscript double-spaced throughout (including title page, abstract, text, references, tables, and legends) on one side only on 22 × 28 cm (8½ × 11 inch) opaque bond paper with 3 cm (1¼ inch) margins all around. *This also applies to correspondence.* Type the last name of the first author in the upper right-hand corner of each page, including the title page.
- ☐ Arrange manuscript as follows: (1) title page, (2) abstract, (3) text, (4) references, (5) tables, and (6) legends. Number pages consecutively, beginning with the title page as page 1 and ending with the legend page.
- ☐ A manuscript for an *original article* ordinarily should not exceed 26 double-spaced typewritten pages, and should be proportionally shorter the more illustrations and tables that are included.
- ☐ The *text* for case reports should be *no more* than 4 double-spaced typewritten pages. If tables or illustrations are included, the text must be reduced. The text for a "how to do it" article should be even briefer, but with detailed illustrative material. Case reports and "how to do it" articles that exceed the allowable length will not be considered for publication.
- ☐ Referencing should be selective and pertain directly to the work being reported. Except in collective and current reviews, comprehensive listings serve no useful purpose and utilize valuable space. As a general guide, original articles

should have no more than 20 references; case reports, 8 references; and "how to do it" articles, 5 references.

Title Page

- ☐ Give the paper as short a title as possible. Also submit a short title of 3 or 4 words to be used as a running head. Include only the names of the authors directly affiliated with the work, stating for each the single highest academic degree. Include the name and location of no more than two institutional affiliations.
- ☐ If the paper has been or is to be presented at the annual meeting of The Society of Thoracic Surgeons, the Southern Thoracic Surgical Association, or another scientific organization, provide a footnote giving the name, location, and dates of the meeting.
- ☐ At the bottom of the page, type "Address reprint requests to Dr . . ." followed by the last name, exact postal address with zip code, *telephone number*, and *FAX number* of the author to whom communications, proofs, and requests for reprints should be sent.

Abstracts

- ☐ Provide an abstract *no longer than 175 words* for an original article. Abstracts for case reports and "how to do it" articles should be shorter (50 to 75 words). An abstract must accompany *every* contribution, except for letters to the editor. Include several (3 to 5) keywords to assist in cross-indexing the article

Text

- ☐ Generally, the text should be organized as follows: Introduction, Material and Methods, Results, and Comment.
- ☐ Cite references, illustrations, and tables in numerical order in the text. (Order of mention in text determines the number given to each.)
- ☐ Spell out, or define in parentheses, all abbreviations, even if they are commonly employed.
- ☐ Give all measurements and weights in *Système International (SI) units*. See "SI Unit Implementation—the Next Step" (*JAMA* 1988;260:73–6).
- ☐ For statistical nomenclature and data analysis, follow the "Guidelines for Data Reporting and Nomenclature" published in *The Annals of Thoracic Surgery* (1988;46:260–1) and found in the program book for the annual meeting of The Society of Thoracic Surgeons.
- ☐ Type footnotes at the bottom of the manuscript page on which they are cited. Credit suppliers of drugs, equipment, and other material described at length in the paper in footnotes, giving company name and location.
- ☐ Type acknowledgments, including complete grant or subsidy information, at the end of the text before the references.

References

- ☐ Identify references in the text using arabic numerals in parentheses on the line. Do not cite personal communications, manuscripts in preparation, and other unpublished data in the reference list. They may be mentioned in the text in parentheses.
- ☐ Type references double-spaced on a separate sheet. *Number consecutively in the order in which they are mentioned in the text.*
- ☐ Journal references should provide *inclusive* page numbers; book references should cite *specific* page numbers.
- ☐ Double-check references for accuracy, completeness, and nonduplication.

(Continued)

- ❑ Abbreviations of journals should conform to those used in *Index Medicus*. The style and punctuation of the references should follow the formats outlined below:

Journal Article

8. Grillo HC, Suen HC, Mathisen DJ, Wain JC. Resectional management of thyroid carcinoma invading the airway. *Ann Thorac Surg* 1992;54:3–10.

(List *all* authors if 6 or fewer; otherwise list first 3 and add “et al.”)

Chapter in Book

12. Vouhé PR. Transplantation of thoracic organs in children. In: Fallis JC, Filler RM, Lemoine G, eds. *Pediatric thoracic surgery*. New York: Elsevier, 1991:319–29.

Book (Personal Authors or Editors)

18. Shields TW, ed. *Mediastinal surgery*. Philadelphia: Lea & Febiger, 1991:1–10.

Tables

- ❑ Tables should be typewritten *double-spaced* on separate sheets, each with a table number (arabic) and title above the table and explanatory notes and legends below. Provide a key in alphabetical order to each table to identify all abbreviations used; this key should be placed below any explanatory notes.
- ❑ Include written permission from *both the author and the publisher* to reproduce any previously published table(s).
- ❑ Tables should be self-explanatory, and the data should not be duplicated in the text or illustrations. If a table provides redundant information, it will be deleted.

Legends

- ❑ Type legends double-spaced on a single sheet. Numbers should be arabic and correspond to the order in which the illustrations occur in the text. Identify (in alphabetical order) all abbreviations appearing in the illustrations at the end of each legend. Give the type of stain and magnification power for all photomicrographs.
- ❑ Include written permission from *both the author and the publisher* to reproduce any previously published illustration(s).
- ❑ Enclose signed releases for recognizable (unmasked) photographs of human beings.

Illustrations

- ❑ Submit *triplicate* sets, each set in its own envelope, of *unmounted* and untrimmed black and white professionally prepared glossy prints. Components of the same illustration (eg, parts A and B) should be submitted separately. Photographs, rather than original art or photocopies, should be provided. All lettering should be done professionally and should be of adequate size to retain clarity after reduction (*final* lettering size in print should be 1.5 mm high). Illustrations will be reproduced at a width of one column (8.25 cm, 3¼ inches) or

two columns (17.15 cm, 6¾ inches), or at an intermediate width ranging from 10.16 to 12.07 cm (4 to 4¾ inches).

- ❑ Many computer-generated illustrations are unsatisfactory for reproduction and should be professionally redrawn. Roentgenogram reproductions should be no smaller than 13 × 18 cm (5 × 7 inches).
- ❑ Place the first author's last name, the figure number, and an arrow indicating the *top* on a gummed label on the back of each illustration.
- ❑ If color illustrations are to be considered for publication, submit *both* positive 35-mm transparencies and color prints. Part of the printing costs for color illustrations will be borne by *The Annals*; however, the author must be prepared to pay \$1,150 for the first color illustration on each page and \$250 for every additional color illustration on the same page.

Human Investigation

- ❑ Include the date of approval by the local institutional human research committee or the ethical guidelines that were followed by the investigators in the Material and Methods section of the manuscript.

Humane Animal Care

- ❑ The Material and Methods section must contain a statement assuring that all animals have received humane care in compliance with the “Guide for the Care and Use of Laboratory Animals” published by the National Institutes of Health (NIH Publication No. 85-23, revised 1985).

Conflict of Interest

The Annals expects authors to disclose any commercial association that might pose a conflict of interest in connection with this manuscript. All funding sources supporting the work should be acknowledged in a footnote. Institutional or corporate affiliations of the authors that might constitute a conflict should be brought to the attention of the Editor.

Scientific Responsibility Statement

Before publication of an accepted manuscript, each author will be required to certify that he or she has participated sufficiently in the work to take responsibility for a meaningful share of the content of the manuscript, and that this participation included:

- (a) conception or design of the experiment(s), or collection and analysis or interpretation of data;
- (b) drafting the manuscript or revising its intellectual content; and
- (c) approval of the final version of the manuscript to be published.

Exclusive Publication Statement

I certify that none of the material in this manuscript has been published previously, and that none of this material is currently under consideration for publication elsewhere. This includes symposia, transactions, books, articles published by invitation, and preliminary publications of any kind except an abstract of 400 words or fewer.

(Author's Signature)

Guidelines for the Submission of Electronic Manuscripts

- ☐ Please note that only the final accepted revision of a manuscript should be submitted as an electronic file. If you are planning to submit a manuscript in this format, please check box.

I. Keyboarding of Manuscripts

- 1) Our equipment can handle the following programs (any version) in their "native" format:

IBM Compatible

DisplayWrite	Q & A Write
Executive Writer	Samna
Leading Edge	Spellbinder
MicroSoft Word	Volkswriter
Multimate	WordPerfect
Office Writer	WordStar
PC Write	WordStar 2000
PFS: Write	Xywrite
PFS: Professional	

Macintosh (do not use "Fast Save")

MacWrite
Microsoft Word
WordPerfect

Other word processors should be saved as ASCII files. For files saved as ASCII, consult the editorial office regarding the keyboarding of attributes such as bold, underline, superscript, subscript, etc.

- 2) All design considerations for typefaces, page layout, and artwork will be handled by the publisher after receipt of the electronic manuscript. **There is no need for the author to input special typesetting codes.**

- 3) Be especially sure to distinguish between the letters O and I and the numbers 0 and 1, respectively.

- 4) A "hard return" results from tapping the keyboard's **Enter** key. Use a hard return only to end a paragraph, or for titles, subheads, separate items on a list, etc. Rely on the word processor's word wrap ("soft return") within paragraphs, list items, etc.

- 5) Use your word processor's capabilities for the following text attributes:

- a) bold
- b) underline and italic
- c) subscript
- d) superscript
- e) strikeout

Text that will be italic in published form may be keyboarded italic or underlined.

- 6) Do not use your word processor's hyphenation capabilities. Do not right justify text. Use two hyphens for long dashes.

- 7) In tables, use only tabs, not spaces, to align columns.

II. Organization and Delivery of Electronic Files

- 1) Accepted manuscripts may be submitted on 3.5" or 5.25" diskettes, which must be either MS-DOS or Macintosh format. The author should retain copies of all files as backup. All diskettes must be accompanied by the *final* revision and a duplicate copy of the manuscript (including two clearly separated and labeled sets of illustrations) in full conformity with the standard Information for Authors on the preceding pages.

- 2) Diskettes should each be labeled with:

- a) author's name
- b) short title of article
- c) operating system
- d) format
- e) word processor used, including version number.

For example, DOS/DSDD/WordPerfect 4.2, or MAC/800K/MS Word v.3. Here, *DOS* and *Mac* indicate the operating system, *DSDD* (double-sided, double density) or *800K* indicates the diskette's physical format, and the remainder indicates the word processor used. Labels for your use are available from the Editorial Office.

- 3) If possible, it is helpful to have additional material such as tables, figure legends, and references saved as individual files—one file for each category. A file key should accompany the diskette.

- 4) Submit only the final accepted version of a manuscript. It is essential that submitted electronic files exactly match the final printout.

- 5) Diskettes should be packed between cardboard (or with foam or bubble-wrap) in an envelope that states that magnetic media is contained.

Please submit your word-processing diskette, the final revision and a duplicate copy of your manuscript, and two clearly separated and labeled sets of illustrations to:

EVENTS OF INTEREST

Brief notices of meetings, courses, and symposia relevant to cardiothoracic surgery are published as a service. They should be formatted as follows: meeting title, date, place, sponsor, accreditation, director, fee, minimum/maximum attendance, and address/phone for further information. Announcements should be sent at least 4 months in advance of publication to *The Annals of Thoracic Surgery*, 3108 Queeny Tower, Barnes Hospital Plaza, St. Louis, MO 63110-1041; telephone, (314) 361-6084.

■ Thirteenth Annual San Diego Cardiothoracic Surgery Symposium, San Diego, California—February 11-14, 1993

For information on this meeting, entitled "Pathophysiology & Techniques of Cardiopulmonary Bypass," contact CREF, PO Box 23220, San Diego, CA 92193; or telephone (619) 541-1444.

■ Forty-second Annual Meeting of the American College of Cardiology, Anaheim, California—March 14-18, 1993

For information on this meeting, contact American College of Cardiology, 9111 Old Georgetown Rd, Bethesda, MD 20814; or telephone (800) 253-4636.

■ Neurohumoral Effects of Profound Hypothermia in Infant Heart Surgery, London, England—March 18-19, 1993

For information on this meeting, contact The Postgraduate Centre, National Heart and Lung Institute, Dovehouse St, London SW3 6LY, England; or telephone 071-351 8172 (facsimile: 071-376 3442).

■ Le Club Mitrale, Paris, France—March 27-April 3, 1993

For information on this live teleconference, contact Margo Irr, ProMed-

ica International, 620 Newport Center Dr, Suite 575, Newport Beach, CA 92660; or telephone (714) 640-5870, extension 28 (facsimile: (714) 759-6911).

■ One Hundred Thirteenth Annual Meeting of the American Surgical Association, Baltimore, Maryland—April 1-3, 1993

For information on this meeting, contact American Surgical Association, Department of Surgery, CB 7245, University of North Carolina, 136 Burnett-Womack Building, Chapel Hill, NC 27599; or telephone (919) 966-4320 (facsimile: (919) 966-6009).

■ American College of Surgeons, Montreal, Canada—April 25-28, 1993

For information on this meeting, contact American College of Surgeons, 55 E Erie St, Chicago, IL 60611; or telephone (312) 664-4050 (facsimile: (312) 440-7014).

■ Seventy-third Annual Meeting of the American Association for Thoracic Surgery, Chicago, Illinois—April 26-28, 1993

For information on this meeting, contact American Association for Thoracic Surgery, 13 Elm St, Manchester, MA 01944; or telephone (508) 526-8330 (facsimile: (508) 526-4018).

RBRVS and Cardiothoracic Surgery

National physician payment reform, coronary artery bypass demonstration projects that bundle reimbursements, and multimillion dollar budgets for developing new practice guidelines; these are but a few of the current federal initiatives being developed to control the ever-escalating cost of health care. It is true that with a 10% annual growth rate, health care spending could go from 666 billion dollars in 1990 to one trillion dollars in 1995 and 1.5 trillion dollars or 16.4% of the gross national product by the year 2000. By comparison, the total US national budget was only 1.35 trillion in 1990. Add this to the fact that roughly 37 million Americans, most of them employees of small businesses or their dependents, have no health coverage at all and 20 million more are without adequate coverage for health care needs. It is not surprising, therefore, that there were more than 20 bills in Congress this year dealing with health care reform and considerable activity in many states on new health payment plans. Space does not permit detailed discussion of any of these specific programs; I would like, however, to comment briefly on recent cost control initiatives initiated by the Health Care Financing Administration (HCFA).

In 1989 Congress passed the Omnibus Budget Reconciliation Act (OBRA '89). As a result of this Act, the Medicare Fee Schedule under which physicians' work is now being valued was developed. This fee schedule is a result of a study by the Harvard School of Public Health and modified by HCFA after receiving comments from many interested parties, including our specialty. The Health Care Financing Administration released the final rule on November 15, 1991; it became effective on January 1, 1992, and this is the evaluation method currently used to value all physicians' Medicare payments.

One of the primary goals of the Medicare payment policy, in addition to reducing overall federal spending, was to increase payments to primary care physicians, especially general and family practitioners, and reduce

payments to practitioners of procedurally oriented disciplines such as thoracic surgery, ophthalmology, and anesthesia. Based on the Resource-Based Relative Value Scale (RBRVS), HCFA has projected a 27% to 28% increase in Medicare payments to primary care physicians and a 27% to 28% reduction in payments to ophthalmologists, radiologists, and thoracic surgeons during the interval of 1991 to 1996. At our own institution, we have seen a 14% decrease in the average Medicare payments for coronary bypass operations between 1991 and 1992. We anticipate further reduction in payment for these procedures of 16% between 1992 and 1996. Fortunately, because of our geographic situation, we had only a 2% reduction in the same coronary artery bypass Medicare payments from 1987 to 1991. Surgeons in other areas of the country, however, have experienced Medicare payment reductions of up to 29% for the period of 1987 to 1991 due to a number of initiatives including Medicare's "over-valued procedure concept." Thus, cardiothoracic surgeons in some areas of the country may experience Medicare fee reductions for coronary artery bypass of 50% to 55% between 1987 and 1996. Although the foregoing figures are a worst case scenario, HCFA has estimated that 70% of cardiothoracic surgeons will sustain overall reductions in excess of 25%, and 9% will experience a devaluation of more than 50%.

Our Society has been extremely fortunate in having as chairman of its Government Relations Committee Dr George E. Miller, Jr, who has devoted literally thousands of hours of his time over the last six years to this very complicated maze of initiatives in the area of physician payment reform. Dr Miller has testified on many occasions before HCFA and the Physicians Payment Review Commission (PPRC).

Doctor Miller and his very able Vice-Chair, Dr Jack Matloff, along with the other members of our Government Relations Committee, felt that the initial Harvard study under the direction of Dr William Hsiao did not correctly derive the work values (time X's intensity) of many of our cardiothoracic surgical procedures. The Committee felt that there were several reasons for these incorrect work values in the initial Harvard study. First, in the development of the work component of each service, 100 "thoracic and cardiovascular surgeons" were asked to value time and intensity for 22 cardiothoracic and vascular procedures. The names of these 100 surgeons were obtained from the AMA listing of self-declared specialists in thoracic and cardiovascular surgery; therefore, some of the individuals who were surveyed for relative work values either were not boarded in our specialty or were not actively performing the operations they were asked to review. Second, the relative work values for each of the 22 procedures were determined by survey of the "skin-to-skin" time and skin-to-skin intensity of the operation. The intensity value was an estimation for the procedure in

question as it related to the placement of a single-chamber pacemaker with transvenous electrodes. This pacemaker procedure was the single "benchmark" for all cardiac, general thoracic, and vascular procedures. Compared with the benchmark, the work values for the great bulk of our cardiothoracic procedures appeared to our committee to be significantly reduced. A third concern of our committee was the fact that although skin-to-skin times and intensities were surveyed by the Harvard group, the period from the patient's entrance into the operating room until the skin incision was made was estimated at 20 minutes and given a value of half the intensity of performing a history and physical. This seemed to be a significant under-estimate of intensity and time for that particular period. Also, the time and intensity during the period from the closure of the skin to entry into the intensive care unit (approximately 20 to 30 minutes) were not included at all. And, finally, the work intensity during the postoperative stabilization period of a cardiothoracic procedure (first half-hour in the intensive care unit) was, in our opinion, markedly underestimated. All of the foregoing factors lead to a compression of the overall intensity scale, ie, simple procedures ranked too high and many of our very involved procedures ranked too low.

There was a second review of these work intensities by a small group of cardiothoracic surgeons, and again, our Government Relations Committee was concerned about the amount of data that were obtained by estimation rather than actually determining precise time and work intensity factors for most of the operations we perform.

The Government Relations Committee and the elected leadership felt that the Harvard study submitted to HCFA needed further modification, and our Society, in turn, commissioned in 1989 a new, very detailed time-intensity evaluation of approximately 45 cardiothoracic procedures by Abt Associates, Inc, of Cambridge, MA. Abt surveyed more than 200 cardiothoracic surgeons from our Society on these 45 surgical procedures. Careful attention was paid to the work intensity of not only skin-to-skin activity, but also the high-risk, high-intensity work periods immediately before and after the intrathoracic activity. The Abt study concluded that the Harvard study had undervalued general thoracic procedures by 4%, vascular procedures by 18%, and cardiac procedures by 25%. This study was submitted by our Society to HCFA; initially, it was praised by both HCFA and PPRC, but subsequently when HCFA released the final fee schedule on November 15, 1991, we found that few of the Abt study determinations were adapted to the HCFA payment schedule. The actual modifications in HCFA's final rule of November 1991 resulted in general thoracic procedures being upgraded by roughly 2%, vascular procedures by 4.5%, and cardiac procedures by 3%. Because of HCFA's concern regarding the validity of the 1992 fee schedule, HCFA termed the final rule "an interim rule" and invited further comments to be submitted by March 25, 1992. Following receipt of these comments, "Refinement Panels" were convened in May 1992, during which representatives of each specialty met with panels consisting of members of HCFA, their regional payment intermediary medical di-

rectors, and representatives of other medical specialties. During these panel meetings, each procedural code addressed in the specialties' refinement comments was reviewed. As of this writing, it is our understanding that the latest iteration of the final rule, which will become effective January 1, 1993, will be published later this Fall and will reflect the results of all input to date.

With an annual "ratcheting down" of Medicare payments for most of our current surgical procedures over the next four years, one of the few areas for budgetary expansion might relate to the volume of procedures performed. Thus HCFA has established the concept of Volume Performance Standards that allow for very modest growth of procedural volume countrywide each year.

Cardiothoracic surgeons in certain areas of the country who have clinical practices without a high percentage of Medicare patients will probably not experience a significant budgetary turndown. On the other hand, cardiac groups doing principally coronary artery bypass surgery in certain areas of the country may sustain a fairly severe reduction in practice income during the period from 1987 to 1996. This will be particularly difficult for academic cardiothoracic programs in those same geographic areas. With the very marked reduction in NIH research funding, most of us involved with university-based cardiothoracic residency training programs support, to a considerable degree, our research laboratories from patient income. Clearly, the funding of cardiothoracic research in most university centers will be reduced during the remainder of this decade. Also during the congressional session just completed there were new bills, considered but not passed, that would preferentially "weight" direct Medicare graduate medical education payments to hospitals to financially favor training slots for primary care physicians as opposed to procedurally oriented physicians. These new congressional initiatives will certainly reappear in new health care reform bills in 1993; the clear intent by Congress is to increase the funding for pediatric, internal medicine, and family practice training programs and reduce funding for surgical training programs. These potential budgetary reductions for thoracic surgical training come at a time when the Joint Conference on Graduate Training in Thoracic Surgery has just recommended increasing the training period in our specialty from two to three years. Facilitating this change in thoracic training over the next few years may be more difficult because of a reduction in direct Medicare funding to hospitals.

Our Society has been very fortunate in having highly dedicated members of the Government Relations Committee. In addition to the Chairman and Vice-Chairman, I need to single out two other members, Dr Sidney Levitsky and Dr Thomas Bartley, who have devoted a great amount of time to the activities of the Committee. These individuals have presented accurately and carefully the concerns of thoracic surgeons over the last several years to the critical health care agencies in Washington. Doctor Miller and his committee feel, though, that at the present time with all of the potentially restrictive health care mandates on the horizon, it is essential for our Society to select a full-time, Washington-based representative dedi-

cated and committed to our specialty's interest. In a recent mail survey of our Society's members, 94% of the 393 respondees supported a more active political stance by The Society. At the last meeting of The Society of Thoracic Surgeons Council in mid-October, there was a unanimous decision to proceed with the concept of full-time representation for our specialty in Washington.

Obviously, our specialty will see some major changes during the rest of this decade; changes in the organization of our clinical practices, changes in cardiothoracic training programs, and changes in the type and the amount of cardiothoracic research. It is apparent that it will be

important for our Society to become very proactive in the medical initiatives of the new Clinton administration.

Incidence and Recurrence of Gastrointestinal Cytomegalovirus Infection in Heart Transplantation

Francisco A. Arabia, MD, Luis J. Rosado, MD, Casey L. Huston, MD, Gulshan K. Sethi, MD, and Jack G. Copeland III, MD

Section of Cardiovascular and Thoracic Surgery, University of Arizona College of Medicine, Tucson, Arizona

Cytomegalovirus (CMV) infection of the upper gastrointestinal tract is a major cause of morbidity in heart transplant recipients. Since April 1985, 201 patients underwent heart transplantation at our institution. Immunosuppressive therapy was with a triple drug regimen of cyclosporin A, prednisone, and azathioprine. Fifty-three of these patients had upper gastrointestinal symptoms, which primarily consisted of abdominal pain or nausea and vomiting despite prophylactic treatment with antacids, H_2 blockers, or both. A total of 79 esophagogastroduodenoscopies were performed in this group; 15 patients required more than one esophagogastroduodenoscopy for recurrent symptoms. Of these 53 patients with persistent gastrointestinal symptoms, 16 (30.2%) had diffuse erythema or ulceration of the gastric mucosa (14), esophagus (1), and duodenum (1) with biopsy results that were positive for CMV on viral cultures

(incidence, 8%). All patients with positive biopsy results were treated with intravenous ganciclovir at a dose of $10 \text{ mg} \cdot \text{kg}^{-1} \cdot \text{day}^{-1}$ in two divided doses for a period of 2 weeks. Recurrence developed in 6 patients (37.5%) and necessitated repeated therapy with ganciclovir. None of the 16 patients died as a result of gastrointestinal CMV infection. Patients who were seronegative for CMV and received a seropositive heart experienced earlier clinical manifestation of CMV infection. Infection of the upper gastrointestinal tract with CMV is a major cause of morbidity in cardiac transplant patients that may progress to a life-threatening complication if left untreated. Early diagnosis with esophagogastroduodenoscopy and biopsy for viral cultures is essential for documentation and proper management.

(*Ann Thorac Surg* 1993;55:8-11)

Cytomegalovirus (CMV), a member of the herpesvirus group, is a ubiquitous virus that can be transmitted through a variety of ways including virus-infected grafts [1]. It is believed that 50% to 80% of adults carry the virus; however, it is almost always latent and asymptomatic unless the carrier becomes immunologically compromised. Transplant recipients in whom an active CMV infection develops from a contaminated organ appear to require a course of immunosuppression to manifest the infection [2].

Series of CMV infection in the transplant population demonstrate an incidence between 15% and 100% [3, 4]. Manifestations of CMV infection include pneumonitis, retinitis, gastrointestinal ulceration and hemorrhage, hepatitis, bone marrow suppression, central nervous system disease, and fever. Cytomegalovirus also predisposes the transplant recipients to infection by other organisms. Mortality in the heart and heart-lung transplant patients with symptomatic CMV infection has been reported to be between 29% and 40%. With the addition of cyclosporin A to the immunosuppressive regimens, it appears that the morbidity of symptomatic CMV infections and the mortality of all infections have been reduced [5, 6].

Gastrointestinal manifestations of CMV infection in the immunosuppressed transplant population have been described involving the esophagus, stomach, duodenum, and colon. The histologic and pathologic appearance of CMV infection involving the gastric mucosa has been documented [7]. In this series, the clinical presentation, diagnostic management, therapy, and outcome of CMV infection of the upper gastrointestinal tract in heart transplant recipients are described.

Material and Methods

From April 1985 to May 1991, 201 patients underwent 205 heart transplantations, including one in the heterotopic position (Table 1). Mean age at transplantation was 46.4 years (range, 2 days to 66 years). There were 175 male and 26 female patients. Serologic test for CMV using immunofluorescence assay was performed in serum samples of donors and recipients at the time of transplantation. The 30-day operative mortality was 3.5%. Average follow-up period was 38.0 months (range, 4 to 77 months).

The immunosuppression regimen consisted of cyclosporin A, azathioprine, corticosteroids, and rabbit antithymocyte globulin. Preoperative cyclosporin A was administered orally at a dose of 4 mg/kg , and administration was continued postoperatively at $5 \text{ mg} \cdot \text{kg}^{-1} \cdot \text{day}^{-1}$ to keep serum levels between 300 and 350 ng/mL. Azathioprine was given orally at a preoperative dose of 4 mg/kg and continued postoperatively at 2 to 3 mg

Presented at the Twenty-Eighth Annual Meeting of The Society of Thoracic Surgeons, Orlando, FL, Feb 3-5, 1992.

Address reprint requests to Dr Arabia, Section of Cardiovascular and Thoracic Surgery, University of Arizona, 1501 N Campbell Ave, Tucson, AZ 85724.

Table 1. Indication for Heart Transplantation (205 transplants in 201 patients)

Preoperative Diagnosis	No. of Patients (%)
Ischemic	92 (45.8)
Idiopathic	67 (33.3)
Viral	17 (8.5)
Congenital	9 (4.5)
AGAS	4 (2.0)
Postpartum	1 (0.5)
Other	11 (5.5)

AGAS = accelerated graft atherosclerosis.

$\text{kg}^{-1} \cdot \text{day}^{-1}$. Methylprednisolone, 500 mg, was administered intraoperatively and continued at 125 mg intravenously every 12 hours for the first 24 hours. After this period, prednisone administration was started at a dose of $1.5 \text{ mg} \cdot \text{kg}^{-1} \cdot \text{day}^{-1}$ and tapered to $0.5 \text{ mg} \cdot \text{kg}^{-1} \cdot \text{day}^{-1}$. Rabbit antithymocyte globulin was administered intramuscularly at a dose of 200 mg every day for the first 3 days, except in the neonate recipient who did not receive rabbit antithymocyte globulin.

Intravenous human immune globulin was given at a dose of $1 \text{ g} \cdot 10 \text{ kg}^{-1} \cdot \text{day}^{-1}$ for 7 days. Patients also received prophylaxis against the probable association of corticosteroids and ulceration of the upper gastrointestinal tract with antacids, H_2 blockers, or both.

During this period of time, 53 patients underwent a total of 79 esophagogastroduodenoscopies (EGDs). These patients' primary symptoms were midepigastic or right upper abdominal pain with or without persistent nausea and vomiting. One patient had an acute abdomen and another had upper gastrointestinal bleeding. Biopsies of the gastrointestinal mucosa were performed whenever diffuse mucosal erythema, ulceration, or nodules were observed. The presence of CMV was confirmed by growing the virus in culture media, or by immunofluorescent studies using murine anti-CMV antigen monoclonal antibodies in mucosal tissue preparations.

Intravenous therapy with ganciclovir was initiated when the CMV infection was documented. The initial dose was $10 \text{ mg} \cdot \text{kg}^{-1} \cdot \text{day}^{-1}$ over 14 days. After this initial treatment, if the patient continued to be symptomatic, ganciclovir therapy was extended for another 14 days.

Results

Of the 201 patients, 16 had development of CMV infection of the gastrointestinal tract (incidence, 8%). The presenting symptoms in these 16 patients were variable. The most common presenting symptom (6 patients) was diffuse upper abdominal pain sometimes radiating to the right upper quadrant. In addition, 3 patients had similar abdominal pain associated with nausea and vomiting, and 2 had only nausea and vomiting. Two patients had diffuse upper abdominal pain associated with fever. One patient had abdominal pain and hiccups. One patient was admit-

ted with a bleeding gastric ulcer, and 1 patient had an acute abdomen. Exploratory laparotomy in the latter patient revealed a perforated pyloric ulcer and an inflamed gastric mucosa.

Cytomegalovirus serology for donors and recipients was obtained at the time of transplantation (Table 2). There were 3 patients who were seropositive and received seropositive hearts. Seven recipients were seronegative and received seropositive hearts. Five patients were seropositive and received seronegative hearts, and only 1 patient was seronegative and received a seronegative heart.

Fifteen patients had the diagnosis of CMV infection of the upper gastrointestinal tract made from mucosal biopsies at the time of EGD. Only the patient with the perforated pyloric ulcer had the diagnosis made from the biopsy at the time of the exploratory laparotomy. Midepigastic pain developed in this patient 9 months later. Esophagogastroduodenoscopy with biopsy revealed recurrent CMV gastritis. Fourteen patients had documented gastritis at the time of the EGD. In addition to the gastritis, 2 patients had esophagitis and duodenitis, 1 patient had duodenitis, 1 patient had severe ulcerative esophagitis, and 1 patient had a bleeding gastric ulcer (see Table 2).

The mean interval between transplantation and the first episode of CMV infection for the entire group was 10.6 months (range, 1.2 to 56.9 months). The average interval for the 7 patients who were seronegative and received a seropositive heart was only 2.0 months. The average interval for the other 9 patients was 17.3 months ($p < 0.01$; Mann-Whitney U test). The average cumulative dose of ganciclovir for all patients for the first documented CMV infection was 13.4 g (range, 6.3 to 22 g). Three patients required modification of the initial dose: in 2 patients because of development of neutropenia and in 1 patient because of deteriorating renal function. Six patients (37.5%) experienced at least one recurrence. Average period for first recurrence was 2.6 months (range, 0.13 to 8.4 months). All the recurrent infections were diagnosed as gastritis except in 1 patient who also had duodenitis. Two patients experienced a second recurrence, and 1 of these experienced third and fourth recurrent infections. This last patient was treated with additional ganciclovir for a period of 28 days. The subgroup of patients with recurrence was small, and risk factors for recurrence have not been identified.

None of the 16 patients with CMV infection died as a result of the CMV infection. The actuarial survival (Cutler-Ederer method using the Gehan test) for the patients who had gastrointestinal CMV infection and those patients who did not have gastrointestinal CMV infection was not significantly different (Fig 1).

Comment

Cytomegalovirus infections can affect all transplant recipients and any other patient who is immunosuppressed. Cytomegalovirus infection either may be reactivated if the recipient was already seropositive or may develop as a

Table 2. Patients With Upper Gastrointestinal Cytomegalovirus Infections

CMV = cytomegalovirus.

primary infection if the recipient was seronegative. Since the advent of cyclosporin A the frequency of symptomatic infections has decreased, although it appears that heart recipients had CMV infections more often than patients who received liver and renal transplants [8]. The morbidity and mortality associated with CMV infection usually are secondary to superinfections by bacterial and fungal agents [9].

Cytomegalovirus in our heart transplant population was recovered on 89 occasions from various bodily fluids (blood, urine, nasopharyngeal, tracheobronchial aspirations; and gastrointestinal biopsy specimens). The upper gastrointestinal tract was the most common source.

Multiple agents including intravenous immunoglobu-

lin, interferon, acyclovir, and a CMV vaccine have been evaluated to treat CMV infection. Winston and associates have suggested that the immune globulin may have some prophylactic efficacy against CMV; however, its efficacy in the treatment of CMV infections has not been established [10, 11].

Ganciclovir (9-[2-hydroxy-1-(hydroxymethyl)ethoxymethyl] guanine) appears to be the agent of choice in the treatment of established CMV infections, especially for the treatment of CMV infections affecting the gastrointestinal tract [12]. Ganciclovir is an acyclic nucleoside that has been shown to be effective against laboratory and clinical strains of CMV [13]. It inhibits DNA polymerase and in this way prevents replication of the virus. However, it does not eliminate the virus from the host. Therefore, recurrences of CMV infections are always possible. Adverse reactions described with the use of ganciclovir are uncommon but include neutropenia, thrombocytopenia, impaired renal function, grand mal seizure, and hypotension [14]. Renal function should be taken into consideration when calculating the appropriate dosage, and frequent white blood count monitoring is also advisable.

Endoscopy of the upper gastrointestinal tract is essential in cardiac transplant patients with upper abdominal complaints. Examination and viral cultures of the gastrointestinal mucosa are of extreme importance to confirm the correct diagnosis.

Cytomegalovirus infections may be associated with accelerated graft atherosclerosis. In a review of heart transplant recipients, accelerated graft atherosclerosis was found to be significantly more severe in the CMV infec-

Fig 1. Actuarial survival of 185 patients without cytomegalovirus (CMV) infection and 16 patients with gastrointestinal (UGI) CMV infection.

tion group [15]. Six of our patients with CMV infections of the upper gastrointestinal tract have been found to have accelerated graft atherosclerosis. However, this series is not large enough to reach a conclusion regarding a relation between CMV infections and accelerated graft atherosclerosis or rejection.

In summary, 201 patients underwent heart transplantation at our institution. Fifty-three patients had abdominal findings requiring EGD and 1 patient needed an exploratory laparotomy. For the patients who required EGD, the diagnosis of CMV infection of the upper gastrointestinal tract was made with mucosal biopsies. One patient required biopsy of a perforated pyloric ulcer for diagnosis of CMV infection. Patients who were seronegative for CMV and received a heart of a seropositive donor had earlier manifestations of upper gastrointestinal tract CMV infections. All patients were treated with ganciclovir for a minimum of 2 weeks. Recurrences occurred in 37.5% and were treated with repeated doses of ganciclovir. No maintenance ganciclovir was required between episodes. There was minimal morbidity in this group associated with the use of ganciclovir and no mortality associated with CMV infections. Infection of the stomach was the most common manifestation of CMV in this group of patients, and the stomach was the most common site of recurrence. Early diagnosis should be made with EGD and mucosal biopsies. Ganciclovir is the treatment of choice at this time.

DISCUSSION

DR WALTER H. MERRILL (Nashville, TN): In some centers the 2-week treatment is routinely followed by another 2 weeks at a lower dose of ganciclovir, and I noticed that you did not do that in your center. Could you comment on the treatment protocol?

DR ARABIA: We followed up these patients in two different ways. First, we followed them up symptomatically during that first period of 2 weeks and then by repeat endoscopy. If at the time of endoscopy, we found no evidence of inflammation, the

cultures were negative, and the patient was symptomatically better, we did not continue therapy.

DR MERRILL: Did you come up with a diagnosis or cause of abdominal distress in those patients who did not have cytomegalovirus infection?

DR ARABIA: Yes, there were a large number of patients who ended up having peptic ulcer disease and nonspecific gastritis.

Leukocyte Depletion in a Neonatal Model of Cardiac Surgery

Ian C. Wilson, MB, ChB, Joseph M. DiNatale, A. Marc Gillinov, MD, William E. Curtis, MD, Duke E. Cameron, MD, and Timothy J. Gardner, MD

Division of Cardiac Surgery, The Johns Hopkins Medical Institutions, Baltimore, Maryland

Neonatal cardiac surgical procedures continue to be associated with a considerable incidence of severe post-operative ventricular dysfunction. The role of neutrophils in mediating such injury has recently been proposed but remains controversial. The present study was undertaken to examine the potential benefits of leukocyte depletion for myocardial preservation using an *in situ*, *in vivo* porcine model of neonatal cardiac surgery. Sixteen 3- to 5-day-old piglets, 8 controls and 8 leukocyte-depleted animals (LD group), underwent 90 minutes of hypothermic ischemia. Mechanical leukocyte filtration during cardiopulmonary bypass reduced the granulocyte count in the initial perfusate to 0.7% of controls. This

was associated with a reduction in leukocyte sequestration in the coronary vascular bed ($p < 0.005$), a decrease in myocardial creatine kinase release ($p < 0.02$), and a reduction in coronary vascular resistance ($p < 0.03$). These changes in physiological response to ischemia were associated with improved postischemic recovery of left ventricular systolic function in LD animals ($p < 0.05$), although there was no significant improvement in diastolic function. Application of this technique in neonatal cardiac operations may improve myocardial protection and reduce the associated morbidity and mortality.

(*Ann Thorac Surg* 1993;55:12-9)

Although neutrophils are involved primarily in the maintenance of the immune system, under certain conditions of altered physiology they may cause damage to host tissue. The accumulation of polymorphonuclear leukocytes in myocardium after ischemia has been recognized for many years [1]. However, their pathogenic role in myocardial ischemia/reperfusion injury remains unclear.

Neutrophils have been implicated in the etiology of irreversible myocyte injury after coronary reperfusion in studies demonstrating a decrease in myocardial infarct size associated with a reduction in neutrophil population or neutrophil function [2, 3]. In contrast, their role in reversible postischemic ventricular dysfunction is still controversial [4, 5], with alteration of neutrophil function and population leading to differing results. However, the interaction of cardiopulmonary bypass (CPB) and myocardial ischemia in cardiac operations may change the response of neutrophils to ischemic myocardium and increase the susceptibility of the heart to injury.

This study examines the effect of mechanical leukocyte depletion during ischemia and reperfusion on postischemic myocardial function in an *in situ*, *in vivo* porcine model of neonatal cardiac surgery.

Material and Methods

Three- to 5-day-old farm-raised Yorkshire-Hampshire cross piglets were separated from the sow on the day of the experiment. All animals received humane care in compliance with the "Principles of Laboratory Animal Care" formulated by the National Society for Medical Research and the "Guide for the Care and Use of Laboratory Animals" published by the National Institutes of Health (NIH Publication No. 85-23, revised 1985).

Piglets were premedicated with ketamine hydrochloride (44 mg/kg), and anesthesia was induced by inhalation of 2% isoflurane. A tracheostomy was performed, the trachea was intubated, and mechanical volume ventilation was initiated with an inspired oxygen fraction of 1.0. Maintenance anesthesia was provided by isoflurane inhalation (0.5% to 1.0%). The femoral artery and vein were cannulated to record systemic arterial and venous pressures.

A median sternotomy was performed, and the ductus arteriosus was ligated. Both vagal nerves were then divided to reduce the autonomic reflex influence of left ventricular (LV) function. Heparin sodium (3 mg/kg) was given before proximal ligation of the hemiazygos vein and insertion of an 8F catheter downstream into the coronary sinus. The distal coronary sinus was then ligated at its junction with the right atrium. Coronary sinus flow was returned to the piglet through an 8F catheter positioned in the distal superior vena cava. Coronary flow was measured by an ultrasonic transit-time flow probe (Transonic 2R; Transonic Systems Inc, Ithaca, NY) placed in line with the coronary sinus catheter.

Pulse transit ultrasonic dimension transducers (Physio-

logical Monitoring Systems; Duke Medical Center, Durham, NC) connected to a sonomicrometer (model 120; Triton Technology Inc, San Diego, CA) were positioned subendocardially to record the LV short-axis dimension. Instantaneous LV pressures were recorded by a Millar micromanometer catheter (model PC-350; Millar Instruments, Houston, TX) passed into the ventricle through its apex. Tapes were placed around both the inferior and superior venae cavae to allow manipulation of ventricular preload during evaluation of ventricular function.

Pressure manometry catheters were positioned in the left atrium through its appendage and in the pulmonary artery through the right ventricular infundibulum. Measurement of cardiac output was achieved by a flow probe (Transonic 8R) placed around the main pulmonary artery.

Systemic temperatures were controlled using a heating/cooling blanket and by adjustment of the perfusate temperature while the animal was on CPB.

Cardiopulmonary Bypass

The CPB circuit was constructed using tubing with an internal diameter of 1/4-inch (6.25-mm) connected to a centrifugal pump head (Bio-Medicus BP-80; Bio-Medicus, Eden Prairie, MN), a temperature-controlled bubble oxygenator (Bentley-5 pediatric blood oxygenator; Bentley American, Irvine, CA), and a pediatric extracorporeal blood filter (Pall LPE-1440; Pall Biomedical Inc, Fajardo, PR) (Fig 1). Leukocyte depletion was achieved in the treatment group by three leukocyte filters (Pall RC100) positioned in parallel on the arterial limb of the bypass circuit.

The circuit was primed with 800 mL of heparinized (3 mg/100 mL) whole blood, and the circulating hematocrit was maintained between 0.25 and 0.28 with lactated Ringer's solution. Vascular access for CPB was attained by inserting a 10F cannula into the descending aorta through the left subclavian artery and by positioning a single right atrial cannula (20F) through the right atrial appendage. Cardiopulmonary bypass was commenced at flow rates of 80 to 100 mL · kg⁻¹ · min⁻¹ with maintenance of a perfusion pressure of 40 to 45 mm Hg and a mixed venous saturation of 70% to 80%. Systemic arterial blood gases were corrected on CPB using alpha-stat control.

Piglets were cooled to 22°C rectal temperature before cross-clamping of the aorta, after which cold crystalloid cardioplegia (20 mL/kg of Johns Hopkins cardioplegic solution) was instilled in an antegrade fashion through the aortic root. Total circulatory arrest was then commenced for closure of the patent foramen ovale. A patent foramen ovale was present in every animal and was repaired by direct suture through a longitudinal right atriotomy. Extracorporeal circulation was resumed after a 30-minute period of total circulatory arrest, after which slow systemic rewarming was commenced before removal of the aortic cross-clamp after 90 minutes of myocardial ischemia. Myocardial temperatures were maintained less than 15°C by the topical application of 4°C saline solution.

Myocardial reperfusion was initiated with warm blood (36°C) at 30 mm Hg perfusion pressure; the pressure was increased gradually over 1 minute to 45 mm Hg. Myocardial reperfusion was continued for 30 minutes in the beating nonworking state before weaning from CPB. Atrial pacing (150 beats/min) was used for all hearts with an intrinsic rate of less than 150 beats/min.

Measurements and Calculations

CORONARY LEUKOCYTE SEQUESTRATION AND MYOCARDIAL CREATINE KINASE RELEASE. Coronary leukocyte sequestration and myocardial creatine kinase release were calculated by measuring the difference between the systemic arterial and coronary venous concentrations of leukocyte count and creatine kinase activity, respectively. Leukocyte counts were measured by Coulter counter analysis (Coulter STKR; Hialeah, FL). Leukocyte sequestration was measured in number of cells per minute per gram of LV wet weight. Creatine kinase activity, measured at 37°C, was measured in international units per minute per gram of LV wet weight.

CORONARY VASCULAR RESISTANCE INDEX. Coronary blood flow was measured at a mean coronary perfusion pressure of 40 to 45 mm Hg. Previous experiments in this newborn model revealed a linear relationship between coronary flow and coronary perfusion pressure in this pressure range. Previous experiments in this model also showed that 90% or more of the coronary sinus blood originated from the left ventricle; therefore, coronary vascular resistance (CVR) was standardized as:

$$\text{CVR (dynes} \cdot \text{s} \cdot \text{cm}^{-5} \cdot \text{g LV weight)}$$

$$= (\text{mean aortic pressure} - \text{mean right atrial pressure})$$

$$\cdot 80/(\text{coronary flow/LV wet weight}),$$

where pressure is measured in millimeters of mercury, coronary flow is measured in liters per minute, and LV weight, in grams.

LEFT VENTRICULAR FUNCTIONAL ASSESSMENT. The indices chosen for analysis of LV function were preload recruitable stroke work (representing overall ventricular performance), end-systolic pressure-volume relationship (representing ventricular systolic function), and ventricu-

lar stiffness (representing an inverse relationship to ventricular compliance). These methods of ventricular functional assessment have been shown to be relatively independent of afterload within the physiological ranges encountered in this in vivo model.

MYOCARDIAL WATER CONTENT. Myocardial water content was calculated after incubation of a section of left ventricle at 100°C for 24 hours. It is represented as percent of LV wet weight.

MYELOPEROXIDASE ACTIVITY. Myeloperoxidase activity was calculated on biopsy specimens taken at completion of the experiment by standard spectrophotometric functional assay. Results are presented in micromoles per 10 mg of wet weight of tissue.

Experimental Protocol

Both the control group ($n = 8$) and the group with leukocyte depletion (LD group; $n = 8$) underwent 90 minutes of hypothermic global myocardial ischemia in an in vivo, in situ model of newborn cardiac surgery. Leukocyte kinetics and indices of myocardial injury were studied during coronary reperfusion. Hemodynamic function and ventricular function were assessed for 60 minutes after discontinuation of CPB.

Six separate piglet experiments were performed (3 controls and 3 LD animals) to provide tissue for ultrastructural analysis of the myocardium. Electron microscopy was performed by a single observer blinded to the treatment groups. Specimens were fixed by coronary perfusion with 4°C 3% glutaraldehyde solution in 0.1 mol/L sodium cacodylate buffer (pH 7.4). The samples were stored in 0.1 mol/L sodium cacodylate solution in 7.5% sucrose (pH 7.4) until processed.

Six piglets (3 controls and 3 LD animals) underwent exchange transfusion to study the effects of large-volume transfusion in this newborn model and to examine the consequences of transfusing leukocyte-depleted blood on vascular resistance and myocardial function in the absence of myocardial ischemia. Animals were exchange-transfused twice their calculated blood volume over 1 hour using fresh heparinized adult porcine blood.

Table 1. Comparison of Age and Weight

Variable	Control	LD
Age (d)	4.9 ± 0.40	4.9 ± 0.35
Body weight (kg)	1.81 ± 0.05	1.85 ± 0.05
Heart weight (g)	18.94 ± 0.98	19.93 ± 0.40

LD = leukocyte depletion.

Statistical Analysis

Results are expressed as the mean $\pm$ the standard error of the mean. Differences between groups were tested for significance by Student's *t* test for unpaired samples or repeated-measures analysis of variance, as appropriate.

Results

Sixteen piglets (8 controls and 8 LD animals) underwent the experimental protocol and were weaned from CPB. The mean age of the groups was similar, as were body weight and heart weight (Table 1). During CPB, a relative leukopenia and granulocytopenia developed in the controls. However, the LD animals showed a marked reduction in circulating leukocytes and granulocytes in the initial coronary reperfusion compared with controls (14.3% and 0.7%, respectively), and a significant reduction in circulating granulocytes was maintained during the entire period of coronary reperfusion ($p \leq 0.0005$). Reappearance of granulocytes in the circulation was apparent in both groups after complete systemic rewarming and discontinuation of CPB, with similar rates of increase in granulocyte numbers in the circulation of both groups (Table 2).

Leukocyte sequestration across the coronary vascular bed was demonstrated in control animals throughout the period of coronary reperfusion with peak accumulation recorded 5 minutes after removal of the cross-clamp ($237 \pm 86 \times 10^3$ leukocytes $\cdot \text{min}^{-1} \cdot \text{g}^{-1}$ of left ventricle) (Fig 2). In contrast, LD animals showed a significant reduction in coronary leukocyte sequestration ($p \leq 0.005$), manifested by demargination during initial reperfusion ($-73 \pm 21 \times 10^3$ leukocytes $\cdot \text{min}^{-1} \cdot \text{g}^{-1}$ of left ventricle) fol-

Table 2. Systemic Arterial White Blood Cell Counts

Measurement ^a	Leukocytes (No. cells $\times 10^3/\text{mL}$)		Granulocytes (No. cells $\times 10^3/\text{mL}$)	
	Control	LD	Control	LD
Prime	$13,146 \pm 1300$	677 ± 150	$6,047 \pm 854$	14 ± 4
Before bypass	$8,633 \pm 797$	$7,324 \pm 469$	$4,426 \pm 603$	$3,619 \pm 470$
Myocardial reperfusion (min)				
5	$4,231 \pm 429$	603 ± 111	552 ± 140	4 ± 2
35	$3,522 \pm 268$	948 ± 140	457 ± 72	31 ± 8
90	$3,270 \pm 366$	965 ± 177	499 ± 90	87 ± 26

^a The first two measurement entries are as follows: prime = white blood cell count in cardiopulmonary bypass circuit immediately before the start of extracorporeal circulation; before bypass = white blood cell count immediately before cardiopulmonary bypass.

LD = leukocyte depletion.

Fig 2. Myocardial leukocyte sequestration across the coronary vascular bed before the onset of cardiopulmonary bypass and during coronary reperfusion. (LD = leukocyte depletion.)

Fig 3. Release of myocardial creatine kinase (CPK) into the coronary venous blood. Release was calculated as the gradient between the systemic arterial and the coronary sinus blood. (LD = leukocyte depletion.)

lowed by minimal sequestration throughout the remainder of the period of observation.

Myocardial myeloperoxidase activity demonstrated significantly greater activity in control piglets ($69 \pm 4 \mu\text{mol}/10 \text{ mg}$ of left ventricle) compared with LD animals ($27 \pm 4 \mu\text{mol}/10 \text{ mg}$ of left ventricle; $p \leq 0.005$) and confirmed the greater accumulation of granulocytes in controls. Previous experiments in which biopsy specimens were taken from hearts before and after flushing with normal saline solution after ischemia and reperfusion revealed no significant difference in myeloperoxidase activity after flushing. This suggests that circulating leukocytes participate little in myocardial myeloperoxidase activity after ischemia.

The pattern of myocardial creatine kinase release during coronary reperfusion was also different between groups. Enzyme release was similar during initial reperfusion ($59.7 \pm 16.0 \text{ IU} \cdot \text{min}^{-1} \cdot \text{g}^{-1}$ of left ventricle in controls and $77.4 \pm 23.8 \text{ IU} \cdot \text{min}^{-1} \cdot \text{g}^{-1}$ of left ventricle in the LD group). However, there was a significant increase in myocyte creatine kinase leakage in controls at 35 and 90 minutes of reperfusion (25.9 ± 3.4 and $44.3 \pm 17.3 \text{ IU} \cdot \text{min}^{-1} \cdot \text{g}^{-1}$ of left ventricle, respectively) compared with LD animals (7.2 ± 5.5 and $3.7 \pm 6.62 \text{ IU} \cdot \text{min}^{-1} \cdot \text{g}^{-1}$ of left ventricle, respectively) ($p \leq 0.02$) (Fig 3).

Coronary vascular resistance index was reduced in both groups during initial coronary reperfusion compared with baseline, but subsequently rose to greater than preischemic values by 35 minutes of reperfusion in controls and remained elevated throughout the remainder of the experiment (Fig 4). In contrast, the LD group showed a gradual increase in coronary vascular resistance index during the experiment, but it never was greater than baseline and remained significantly lower than that in controls ($p \leq 0.03$). Hemoglobin concentrations were similar in both groups (Table 3).

These changes in coronary reperfusion were associated with an alteration in ventricular function. Postischemic recovery of LV performance (preload recruitable stroke work) was improved in the LD animals at 15 and 60 minutes after CPB compared with controls ($70\% \pm 5\%$ and $65\% \pm 4\%$, respectively, in controls, and $96\% \pm 5\%$ and $94\% \pm 6\%$ in LD animals; $p \leq 0.01$) (Fig 5). This was associated with significant improvement in the end-systolic pressure-volume relationship, controls recovering $57\% \pm 6\%$ and $66\% \pm 4\%$ at 5 and 60 minutes, respectively, compared with LD piglets with recovery of $84\% \pm 6\%$ and $89\% \pm 5\%$ at the same time points ($p \leq 0.01$) (Fig 6). However, no significant difference in myo-

Fig 4. Coronary vascular resistance measured before cardiopulmonary bypass (Pre-ischemia) and during coronary reperfusion. These measurements were standardized to the weight of the left ventricle as described in the text. (LD = leukocyte depletion.)

Table 3. Systemic Arterial Hemoglobin Concentration

Group	Before Bypass	Hemoglobin Concentration (g/dL)		
		Start	Reperfusion	90 Minutes
Control	9.6 ± 0.48	10.1 ± 0.42	10.6 ± 0.39	10.7 ± 0.67
LD	9.3 ± 0.60	10.3 ± 0.40	11.0 ± 0.38	10.9 ± 0.21

LD = leukocyte depletion.

cardial oxygen consumption was identified ($p \leq 0.3$) despite similar heart rates in both groups (Table 4).

In contrast to these improvements in ventricular function, ventricular stiffness was not significantly different between groups, and LV water content showed similar increases in both controls ($79.7\% \pm 0.4\%$) and LD animals ($78.96\% \pm 0.5\%$) ($p \leq 0.3$) compared with baseline ($77.9\% \pm 0.2\%$).

Hemodynamic monitoring demonstrated a significant reduction in pulmonary vascular resistance in the LD animals compared with controls over the course of the observation period ($p \leq 0.05$), although there was no significant difference in systemic vascular resistance between groups ($p \leq 0.5$) (Table 5). However, mean pulmonary artery pressure was not significantly different between groups before or after ischemia.

Electron microscopy revealed predominantly reversible myocardial injury in all piglets. There was no increase in irreversible damage in either group.

Exchange transfusion of homologous blood to newborn piglets not undergoing CPB and myocardial ischemia resulted in no significant change from baseline in LV function or CVR. Leukocyte depletion of exchange-transfusion blood also resulted in no significant change in these variables after exchange transfusion.

Comment

The role of neutrophils in ischemia/reperfusion injury of the myocardium remains uncertain, but their ability to cause tissue injury in response to inflammatory mediators is established [7]. Neutrophils are capable of reversible and irreversible cellular injury by release of oxygen-derived free radicals and lysosomal enzymes in response to neutrophil activation. However, whether these mechanisms are important in the etiology of postischemic ventricular dysfunction after a cardiac operation is not known.

Neutrophil-endothelial cell adhesion is critical to neutrophil-mediated tissue injury because it allows sufficiently high concentrations of these cytotoxic agents to accumulate between the neutrophil and endothelial cell. Myocardial ischemia and CPB both promote neutrophil-endothelial cell adhesion, thereby predisposing the myocardium to such an injury.

The release of inflammatory mediators in response to CPB has been known for many years [8]. However, the effect of these mediators on neutrophil adhesion was not known. We have recently documented increased expression of the neutrophil cell surface adhesion receptor subunit CD18 in a newborn model of CPB, suggesting an increased number of neutrophil CD11b/CD18 surface receptors available for neutrophil-endothelial cell interaction (unpublished data). This finding demonstrates that the systemic inflammatory response initiated by the con-

tact of blood with the extracorporeal circuit may predispose the myocardium to neutrophil-mediated tissue injury. Intramyocardial complement activation induced by myocardial ischemia [9] may cause the heart to become a target for these activated neutrophils by opsonizing myocardial endothelium with C3bi and by promoting neutrophil chemotaxis. In response to complement activation or as a direct effect of ischemia, increased expression of endothelial intracellular adhesion molecule and endothelial-leukocyte adhesion molecule after ischemia may further promote endothelial-neutrophil interaction. However, the rate of surface expression of endothelial cell receptors during ischemia is reduced by hypothermia, and the importance of this expression in cardiac surgery is unknown.

The present study demonstrates that leukocyte sequestration occurs within the coronary vascular bed after global hypothermic ischemia in an in vivo, in situ model of cardiac surgery. Leukocyte accumulation during coronary reperfusion began early during myocardial reperfusion and peaked at the first recording, 5 minutes after removal of the cross-clamp. This early myocardial leukocyte sequestration during cardiac operations is similar to that described by Semb and colleagues [10] in 1990. However, in the present study, myocardial leukocyte accumulation continued for the duration of the 90-minute period of coronary reperfusion. Similar temporal patterns of leukocyte accumulation during coronary reperfusion have also been reported in models of myocardial infarction [11], in which rapid early accumulation of neutrophils is followed by progressive deposition, with peak myeloperoxidase activity demonstrable at 6 hours after coronary reperfusion.

The cause of the demargination of leukocytes seen in the LD group during initial reperfusion is unknown. However, this study suggests that leukocytes themselves play a part in the accumulation of neutrophils within the coronary vascular bed by a positive feedback mechanism. The reduction in the circulating leukocyte population appears to reduce the tendency for neutrophils to sequester in the coronary vascular bed. This effect is possibly due to a reduction in local chemotactic agents such as leukotriene B₄, platelet-aggregating factor, or superoxide anions, which are known to be generated by neutrophils during coronary reperfusion [10, 12], or by a reduction in endothelial cell surface expression of adherence receptors. Leukocyte demargination is thereby able to occur early during coronary reperfusion in response to the release of local agents such as adenosine from myocytes or in response to elevated levels of myocardial catecholamines during coronary reperfusion. The reason for the persistent reduction in leukocyte sequestration is presumably a result of the continued reduction in the circulating neutrophil population, which results in reduced neutrophil exposure to the myocardium, combined with a continued reduction of neutrophil-endothelial cell interaction. However, there was an increase in leukocyte sequestration throughout coronary reperfusion in the LD group as circulating leukocytes increased in number, and the effect of late exposure of the myocardium to leukocytes that return to the circulation after the first 60 minutes after CPB is unknown.

Previous experiments have shown that intracoronary instillation of C5a results in a neutrophil-dependent increase in CVR [13]. The present study demonstrated a similar, although less pronounced, leukocyte-dependent

rise in CVR after 90 minutes of hypothermic ischemia. The increased neutrophil-endothelial cell interaction present in both studies may account for these changes in vascular resistance, although the mechanism for such a change is unclear. Previous studies [14] have reported that neutrophil capillary plugging, causing capillary "no-reflow" [15], is a cause of increased CVR after irreversible ischemia. However, there are no such reports after reversible ischemia. Release of local vasoactive substances from neutrophils or the loss of normal endothelial cell function may also account for changes in CVR. Leukotrienes C₄ and D₄ and thromboxane A₂ [16, 17] have been shown to be released during postischemic coronary reperfusion and are capable of local vasospasm. These autacoids can be released by neutrophils or neutrophil-entrapped platelets within the coronary vascular bed and thereby may account for neutrophil-mediated changes in CVR. Alternatively, endothelial cell damage may result in reduced production of local vasodilating agents by the endothelium and increased CVR [18]. Such a neutrophil-dependent reduction in endothelium-derived relaxation factor has previously been demonstrated in the coronary vasculature. Whatever the cause of the increase in CVR, it appears to be mediated predominantly by leukocytes independent of myocardial edema, as myocardial water content was not significantly different between groups. Similar reports of a neutrophil-independent increase in capillary permeability during myocardial ischemia support these observations [19].

The improvement in global LV performance (preload recruitable stroke work) and LV systolic function (end-systolic pressure-volume relationship) seen in this study demonstrates that the accumulation of leukocytes during hypothermic myocardial ischemia and normothermic coronary reperfusion in a model of cardiac surgery is associated with reduction in early postischemic ventricular function. Previous studies [4, 5, 20, 21] examining the effects of mechanical leukocyte depletion on regional postischemic myocardial stunning have provided conflicting results. However, the increased tendency to neutrophil-endothelial interaction in this CPB model may increase the degree of leukocyte accumulation in the coronary vascular bed and thus emphasize the benefits of reducing neutrophil population during ischemia and reperfusion.

The cause of the reduction in postischemic systolic ventricular function induced by leukocyte-dependent myocardial injury is unclear. Previous experiments have documented a neutrophil-dependent reduction in systolic ventricular function in response to C5a administration [13], which is associated with an increase in CVR. This effect appears to be short-lived, with rapid return of CVR and systolic function to normal values after discontinuation of C5a injection. These experiments suggest that the reduction in coronary flow in the control group of this study may be a crucial determinant of systolic ventricular function. However, the local release of cytotoxic compounds from neutrophils may also contribute to myocardial injury. Neutrophil-dependent superoxide anion release has been shown to induce postischemic ventricular

dysfunction in Langendorff preparations, and further experiments are necessary to establish the etiology of the myocardial injury. We recognize the possibility of an alteration of right ventricular-LV interaction, caused by a significantly reduced postischemic right ventricular afterload in the LD group, leading to a spurious difference in preload recruitable stroke work and end-systolic pressure-volume relationship. However, although the pulmonary vascular resistance was reduced significantly by leukocyte depletion, the pulmonary artery pressures were not significantly different between groups, and a large alteration in right ventricular-LV interaction between groups is therefore unlikely.

The degree and duration of leukocyte depletion required to achieve these alterations in ischemia/reperfusion injury and the effect of a temporary reduction in circulating granulocytes on the postoperative immunological response are unknown and need further investigation. Recent studies in our laboratory showed that the circulating granulocyte counts in LD piglets return to 68% of those in control animals by 6 hours postoperatively (unpublished data). Despite this rapid return of granulocytes to the circulation, improved myocardial function was preserved for the first 6 hours after myocardial reperfusion. The early reappearance of granulocytes potentially reduces the risk of postoperative infections. In a model of regional stunned myocardium, other investigators [22] have shown that granulocyte counts of 10% of baseline during early coronary reperfusion were sufficient to induce postischemic ventricular dysfunction. However, further studies are required to better document the degree of leukocyte depletion necessary to reduce postischemic ventricular dysfunction during cardiac operations, although these studies do suggest that preoperative acute plasmapheresis [23], in contrast to perioperative mechanical leukocyte depletion, is unlikely to be beneficial.

These results demonstrate that mechanical depletion of the neutrophil population during hypothermic myocardial ischemia and normothermic coronary reperfusion results in improved preservation of postischemic cardiac physiology and myocardial function. The use of leukocyte depletion in clinical cardiac surgery may thereby improve the results of neonatal cardiac surgery in the future.

DISCUSSION

DR GEORGE L. HICKS, JR (Rochester, NY): My associates and I also are interested in leukocyte filtration but for a different reason. We have seen the possible immunologic effects of transfusions after operation, and you are studying the white cell effect of the filter. What is the exact filtration-pore size of your filter?

Have you looked at the filters and the nature of the cells being trapped? Are you getting white cells, or are you getting a lot of platelets or other debris? I think this may influence what is occurring in your experiment. We do believe that if white cell administration is held to a minimum in the postoperative period, not only can leukocyte injury be decreased but also perhaps the immunologic effects of transfusion components may be decreased.

DR WILSON: Yes, we have examined the filters. I think the function of the leukocyte filter is related more to the polyester fibers than the pore size itself. We may be reducing the platelet

count as well. In this experiment, thrombocytopenia was present in both groups, and there was no significant difference in circulating platelet concentrations between the two groups. However, I cannot disregard the fact that platelet accumulation within the myocardium secondary to leukocyte deposition may well have played a part, and that has been reported previously.

DR RICHARD D. WEISEL (Toronto, Ont, Canada): Dr Wilson, I enjoyed your presentation. I wonder what happens when you finally reperfuse these hearts with normal blood. Are you just delaying rather than ameliorating the detrimental effects of the leukocytes?

DR WILSON: That may well be the case. We have gone on to a further series to look at myocardial function over a 6-hour period, and have found that, in fact, there was no detriment in function over time. These results will be presented eventually.

Subacute Cardiac Rupture: Repair With a Sutureless Technique

José M. Padró, MD, José M. Mesa, MD, Jorge Silvestre, MD, José Luis Larrea, MD, José M. Caralps, MD, Francisco Cerrón, MD, and Alejandro Aris, MD

Cardiac Surgery Units, Hospital de la Santa Creu i Sant Pau, Barcelona, and Hospital "La Paz," Madrid, Spain

Thirteen patients with ages between 53 and 74 years had development of free wall left ventricular rupture after a myocardial infarction (mean interval, 3.8 days). All patients showed clinical signs of cardiac tamponade. Diagnosis was established by bedside multiple pressure monitoring and echocardiography, which showed pericardial effusion with compression of the right ventricle. Cardiac catheterization was not performed. A new surgical technique was employed for the repair. After the pericardium was opened and cardiac tamponade was relieved, the myocardial tear was identified. A Teflon patch was applied over the area and glued to the heart surface with

a surgical glue (cyanoacrylate). Cardiopulmonary bypass was not used except in a patient with a posterior tear. The method was consistently effective in controlling bleeding from the myocardial tear. All patients survived the operation and were discharged from the hospital a mean of 15 days after the operation. Follow-up extending up to 5 years (mean, 26 months) shows a 100% survival, 11 asymptomatic patients, and 2 patients with mild exertional angina. The technique is a simple, effective, and safe method for repair of subacute cardiac rupture and obviates the need for suturing on an infarcted ventricle.

(*Ann Thorac Surg* 1993;55:20-4)

Subacute cardiac rupture after myocardial infarction requires prompt surgical treatment to relieve cardiac tamponade and repair the myocardial tear. Several reports of successful surgical repair have appeared in the literature [1-8], but, in general, the condition has a fatal outcome. A positive step toward improving results was made by Nuñez and associates [9], who, in 1983, reported a technique of covering the ventricular perforation with a patch fixed to normal myocardium with a continuous polypropylene suture. They achieved a 57% survival.

In 1988, our group [10] reported a case of postinfarction cardiac rupture after myocardial infarction successfully treated with a sutureless technique. The myocardial perforation was covered by a Teflon patch fixed to the heart surface by a biocompatible glue. Extracorporeal circulation was not employed. Since this initial report, the technique has proved to be effective in treating this condition. The glue, butyl-2-cyanoacrylate monomer (Histoacryl blue; B. Braun, Melsungen AG, Germany), does not require an activating substance because it polymerizes when it comes in contact with tissue moisture.

In this article, we report the combined results of two centers treating rupture of the free wall of the left ventricle with this sutureless technique. Nine patients were treated at Hospital "La Paz" in Madrid, a center with large experience in treating cardiac rupture [9, 11], and 4 were treated at Hospital de la Santa Creu i Sant Pau in Barcelona, where the technique originated [10].

Material and Methods

Patient Population

Between November 1986 and April 1991, 13 patients were treated surgically for subacute free wall left ventricular rupture after a myocardial infarction. Ages ranged from 52 to 74 years, with a mean of 64.6 years. Eight patients were men and 5 women. Only 1 patient had history of previous ischemic heart disease.

Myocardial rupture developed a mean of 3.8 days after myocardial infarction (range, 0.5 to 7 days). All patients showed sudden cardiac decompensation with typical signs of cardiac tamponade, including hypotension, cyanosis, and jugular ingurgitation. Two patients sustained cardiac arrest, but they were resuscitated.

Diagnosis of subacute cardiac rupture was made by bedside pressure determinations taken through a Swan-Ganz catheter in 11 patients, and it was confirmed by echocardiography in all patients. Echocardiographic findings included the presence of pericardial effusion and diastolic compression of the right ventricle. A positive pericardiocentesis was obtained in the 8 patients in whom it was performed. Hemodynamic improvement was consistent after this procedure, although only for a short time. After the diagnosis was confirmed, all patients underwent surgical treatment without further studies at the cardiac catheterization laboratory.

Surgical Technique

The surgical protocol was essentially the same throughout the series. After a median sternotomy was performed, the pericardium was opened. Blood and clots were evacuated, and this resulted in dramatic hemodynamic improvement. The heart surface was inspected to localize

Fig 1. Blood oozing through a posterior myocardial tear (arrow).

the myocardial tear. This was identified in the inferior or posterior aspects of the left ventricle in 7 patients, in the anterior in 3, and in the lateral wall in the remaining 3 patients. The tear in the epicardium ranged between 6 mm and 2 cm, and in only 2 patients was there active, squirting bleeding. In the remaining, small clots were in the area of rupture and oozing was seen coming from the tear (Fig 1). No cardiopulmonary bypass was employed except in 1 patient with a very posterior tear in whom mobilization of the heart produced severe hemodynamic derangement. After exposure of the tear, a few drops of Histoacryl blue were placed over it at surgeon's discretion. Then, the area was covered by a large patch of Teflon felt (measuring about 8×5 cm) and fixed to the heart surface by a few more drops of Histoacryl. Once in place, the patch covered most of the wall where the perforation had occurred. Extra drops of the glue were applied to the patch over the area of the tear. Due to the porous properties of the felt, this maneuver reinforced the tacking of the material over the heart surface. Once dried (less than 30 seconds), the whole area of the tear had a hard mass consistency (Fig 2). The technique was effective in controlling bleeding in all patients. After hemodynamic stabilization, the chest was closed in a routine fashion, leaving two chest tubes and a temporary pacemaker wire.

Results

There were no operative deaths. Postoperative complications included prolonged ventilatory support resulting in sternal dehiscence in 2 patients, low cardiac output requiring inotropic agents in 2 patients, and seizures in 1 patient. Average length of hospital stay was 15 days, ranging from 5 to 40 days.

Five patients had echocardiograms performed between 3 and 7 months after repair. Dyskinesis of the wall affected by the rupture without evidence of pseudoaneurysm was found in 3. One patient underwent cardiac

catheterization several months after operation for professional reasons (airline pilot). The right coronary artery was occluded (he had an inferior rupture), but the rest of the coronary arteries were free of disease. The left ventricle had good motion. The patient with a prior myocardial infarction, who was operated on more than 5 years ago, recently had an echocardiogram that showed normal ventricular function.

Follow-up extends up to 5 years (mean, 26 months) and shows no late deaths and 11 asymptomatic patients. Two patients have mild exertional angina.

Comment

Cardiac rupture was first described by Harvey in 1647 [12]. Morgagni [13] collected 10 cases in his monumental work published in 1769. More than 200 years later, Bates and associates [12] collected 1,200 cases in the literature and reported 20 of their own.

The incidence of cardiac rupture varies between 4% and 24% of all autopsies performed in patients dying of a myocardial infarction [14-17], although higher numbers have been reported in the literature [18]. Cardiac rupture occurs 4 to 10 times more often than rupture of the interventricular septum or a papillary muscle [12, 15], two well-known mechanical complications of myocardial infarction for which surgical treatment is widely and successfully applied. However, surgical treatment of cardiac rupture is still a challenge to most cardiac surgeons because of the high mortality that occurs even before the diagnosis can be made. Cardiac rupture after myocardial infarction is considered to cause more than 25,000 deaths a year in the United States [12].

The approach to treat this problem must be double: first, an awareness of the disease, which has very precise clinical patterns, may help to diagnose many cases before death occurs; and second, the surgical treatment should

Fig 2. Final aspect of the repair with the patch glued over the area of the tear.

be expeditious, simple, and safe. Our patient population does not differ from those of previously published works. Age of the patients had a mean of 64 years, which is in agreement with most of the reported series [9, 15, 16, 18, 19]. Also, the high prevalence of female patients (5 of 13) has been reported previously [14, 16, 17]. In a series of 47 autopsy cases, London and London [16] found that female patients had a 6.9% chance of cardiac rupture after myocardial infarction as compared with 3.8% for men. Griffith and associates [14] found also that it is more likely to occur in women than in men (54% versus 46%). In one study [20], cardiac rupture was responsible for 30% of the deaths due to myocardial infarction of women with ages between 60 and 69 years.

The time of rupture after myocardial infarction in our series was a mean of 3.8 days, ranging from 0.5 to 7 days, with three ruptures occurring during the first 24 hours. In two different studies, Griffith and associates [14] and Shapira and co-workers [20] found 40% of the patients dying within 24 hours of the infarction, but Bates and colleagues [12] found only 50% of the patients had rupture within 4 days, although 87% had rupture by 14 days.

It seems that there is a substantial percentage of patients in whom rupture occurs not as a sudden, explosive, and fatal episode but as an insidious, progressive entity that reveals itself clinically as cardiac tamponade. This "subacute" rupture [4] may leak blood to the pericardium before massive rupture ensues. In this particular subgroup of patients, surgical treatment is possible and lifesaving. Diagnosis must be suspected in any patient recovering uneventfully of a transmural myocardial infarction in whom chest pain develops with sudden collapse. Several electrocardiographic findings have been described as diagnostic of cardiac rupture: bradyarrhythmias (sinus, nodal), increase of the amplitude of the T wave, reduction of the QRS amplitude, reversal to upright of previously inverted T waves, and right bundle-branch block [18, 19, 21], but none is pathognomonic. Signs of cardiac tamponade (pallor, cyanosis, distended neck veins, quiet heart sounds) are always present. Electromechanical dissociation may appear.

Pericardiocentesis is important in the diagnosis and may be lifesaving [3, 4, 7, 12], but confirmation of the rupture is best done by multiple pressure measurements through a Swan-Ganz catheter and by echocardiography.

Beside hemodynamic findings in subacute ventricular rupture have been studied extensively in one of our centers [9, 11] and are as follows: diastolic equalization of right atrial, pulmonary artery, and pulmonary capillary wedge pressures with right atrial pressure elevation (greater than 10 mm Hg); a deep X descent and blunted Y descent in right atrial pressure curves; a decrease in arterial pressure of more than 10 mm Hg during inspiration; and a decrease in the differential pulmonary artery pressure. Echocardiography is an easy and effective method to confirm cardiac tamponade. The presence of pericardial fluid and diastolic compression of the right ventricle are the two most relevant findings.

Once the diagnosis has been established the patient

should be taken to the operating room without delay. Cardiac catheterization and coronary angiography have been performed before successful surgical treatment in some patients [1, 4, 8], but the risks involved are not outweighed by the benefits. Cardiac rupture occurs in patients with small infarcts [14, 22] and poor collateral circulation [18]. Most of the patients do not have history of previous ischemic heart disease, and the process frequently affects patients with single-vessel disease [9]. Of our patients, only 1 had history of a myocardial infarction before the one that originated the rupture, and the only patient with coronary angiography had normal coronary arteries except for occlusion of the vessel irrigating the area of rupture, as in the patients operated on by Pífarre and associates [8]. The presence of fresh thrombosis in the vessel is a typical finding [16, 18]. However, other authors report severe, generalized disease in cases of cardiac rupture [12, 15]. The left anterior descending coronary artery has been implicated as the responsible vessel in some studies [14, 23], although in our experience, as in that of others [9, 12, 15, 17, 18], cardiac rupture may occur equally in any area of the left ventricle.

The surgical technique must be expeditious and simple. Infarctectomy has been performed with success [1, 4, 5, 7, 8] but involves extracorporeal circulation and suturing on an infarcted ventricle, a situation that can be dangerous and frustrating. Löfström and associates [22] reported a case where a Dacron patch was glued over the area of rupture but it loosened soon. Reinforcement of the sutures with strips of Teflon felt may prevent tearing, but the technique used by Nuñez and associates [9] of covering the area with a large patch and anchoring it to normal myocardium with continuous suture appears safer.

Our modification entails the use of a biocompatible glue. Cyanoacrylate is the basic component of the "super-glues" available for domestic use. Its main advantage is that does not require an activating substance because it polymerizes rapidly when in contact with water or tissue moisture. It comes in liquid form and has a much stronger adhesive capacity than other biological or biocompatible glues that are used mainly for sealant or reinforcement purposes [24, 25]. No toxic effects have been observed.

In our patients a large patch to enhance adhesion to the ventricular wall was applied over the area of rupture and fixed to the heart surface with a few drops of glue in each corner. With more drops over it, the patch became firmly adherent to the epicardium in less than 1 minute. Bleeding was stopped in all patients, and no recurrent hemorrhage appeared.

In summary, subacute cardiac rupture must be suspected in a patient recovering uneventfully of a transmural myocardial infarction in whom chest pain develops with sudden collapse and signs of cardiac tamponade. Surgical treatment must be initiated promptly. The use of a patch applied to the area of rupture and fixed to the heart surface by means of a strong surgical glue is a quick, effective, and safe method to deal with this lethal complication of myocardial infarction.

DISCUSSION

DR FREDERICK A. CRAWFORD, JR (Charleston, SC): We have been interested in this particular technique for closing ventricular septal defects, and applied it in the experimental laboratory. It is true that the patch will stick to the heart, but the adherence seems to be relatively superficial so that you actually tear off layers of the patch. The glue does not come loose, but you simply tear off layers of the myocardium. What is it like when you do this; have you had that experience? Also, do you have any follow-up studies or anything to show whether you have any false aneurysms or anything of that type?

DR ARIS: Well, as I showed in the pictures of the procedure, once you have finished it, the whole thing is like a hard mass. It is almost impossible to tear it out, and we have not seen any detachment. In all patients there was complete control of the bleeding, although there was squirting of blood in only 2 patients. In the rest there was just an oozing.

We had a patient who was an airline pilot, and, for professional reasons, he (and, of course, the company) wanted to know how

his heart was. He had ruptured through an inferior infarct, and the angiogram performed several months later showed an occlusion of the right coronary artery as the only lesion. The rest of his coronary arteries were normal. The ventricular function was fairly good. Also we did echocardiograms in 7 patients, and in 3 we found saccular dilatation of the wall of the ventricle.

DR MOLIARI (New Haven, CT): What are the long-term results if further coronary artery disease develops in these patients and you need to do a reoperation on them? Would you be able to dissect the heart with all this glue attachment around?

DR ARIS: Regarding the long-term results, in 5 years we had only 2 patients with mild exertional angina. One is a very heavy, diabetic woman. In the patients who rupture, when you do an angiogram, as I pointed out, very often there is only one-vessel disease. That does not mean that you cannot have a patient with more than one diseased vessel, but in this case I do not think that

I would be able to go back to do a bypass graft in the area where the patch was glued.

DR CRAWFORD: Would you find this technique useful for a posterior left ventricular rupture after mitral valve replacement? Have you had a chance to use it for that?

DR ARIS: Yes. We did it in 1 patient who had a tear of the posterior wall of the left ventricle. We put on the glue and the bleeding was controlled, but it progressed to other areas. The patient eventually died and we did an autopsy. The pathologist had a hard time trying to detach the patch from the heart.

DR GUS J. VLAHAKES (Boston, MA): Does the material work in a field where there is still active bleeding? How do you get it to adhere to muscle where the bleeding may be rapid enough to wash it off?

DR ARIS: The glue is activated by moisture, so you need a little bit of the moisture of the tissues, but if there is active bleeding, very rapid, the glue does not have time enough to dry and it is washed off from the bleeding area.

DR WILLIAM I. BRENNER (Beverly Hills, CA): I want to congratulate the authors of this report on this excellent technique. I do not know if it is useable in the United States because of our Food and Drug Administration's restrictions on cyanoacrylate glue. I see you have the category of "blow-out leading to death." Occasionally the cardiac surgeon is unfortunate enough to be summoned to the catheterization laboratory for one of these "death" category patients. Do you have statistics on how many patients in this population were considered "dead" because they could not be subjected to this treatment?

DR ARIS: I do not have the exact numbers of patients who had an instant death during the 5 years that we have been using this technique, but that quite often happens, mainly if the patient has a blown-out rupture at 3 o'clock in the morning. You cannot get the surgical team to do the operation, even if you do not need extracorporeal circulation.

I just have one closing remark. We are aware, more than ever, that we do not cure the disease, we just stop the process. But we should keep in mind the saying by Charles Clavel, a French surgeon, who said: "Before we save the function, we must save the functionary."

Human Cryopreserved Homografts: Electron Microscopic Analysis of Cellular Injury

Donald G. Crescenzo, MD, Stephen L. Hilbert, PhD, Robert H. Messier, Jr, MD, Patrick W. Domkowski, MS, Mary Kay Barrick, BS, Perry L. Lange, BS, Victor J. Ferrans, MD, PhD, Robert B. Wallace, MD, and Richard A. Hopkins, MD

Twenty-five human cryopreserved valves with harvest-related warm ischemic times (WITs) ranging from 0 to 20 hours were studied using transmission electron microscopy to characterize the effects of harvesting and preservation on leaflet matrix cells. The valves were divided into seven groups on the basis of WIT and processed using standard transmission electron microscopic methods. Each cell (528 micrographs) was graded for reversible and irreversible cellular injury and subjected to a Cochran-Mantel-Haenszel trend analysis. Our results demonstrated a progression in cellular injury with increasing WIT. During the first 12 hours of warm ischemia, reversible cellular injury predominated (0.0%, 30.0%, 51.2%, 31.3%, 35.1%, 45.1%, and 40.0% at WITs of 0, 1, 2, 8, 12, 16, and 20 hours, respectively). A positive correlation ($p < 0.0001$) between increasing WIT and reversible cellular injury through the first 12 hours was

observed. Minimal morphologic evidence of irreversible injury was noted in valves harvested with less than 12 hours of warm ischemia; however, after 12 hours there was a marked increase (0.0%, 0.0%, 4.7%, 2.4%, 2.7%, 31.4%, and 40.0% at WITs of 0, 1, 2, 8, 12, 16, and 20 hours, respectively) in irreversible cellular injury ($p < 0.001$ between 12 and 20 hours WIT). These data demonstrate a progression in cellular injury with increasing WIT. There was virtually no morphologic injury in valves with harvest-related WITs less than 2 hours and minimal irreversible cellular injury observed in valves exposed to 12 hours or less of warm ischemia. If cellular viability is critical to homograft durability then harvest-related warm ischemia may need to be restricted to 12 hours.

(*Ann Thorac Surg* 1993;55:25-31)

Currently, there are three categories of prostheses available, with the selection of a specific replacement heart valve design being dictated by clinical indications, patient factors, and surgeons' preference. Although the ideal cardiac valve replacement has yet to be identified, the human cryopreserved homograft offers numerous clinical advantages for ventricular outflow reconstruction over both mechanical and xenograft valves: (1) relative resistance to endocarditis; (2) optimal hydraulic performance especially in the small aortic root size of children; (3) low incidence of thromboembolic complications; and (4) freedom from long-term anticoagulation and superior performance in the right ventricular outflow tract position [1]. Long-term durability of the homograft, although uncertain, seems to be influenced by the preimplantation processing method chosen (Fig 1). Historically,

the spectrum of these methods ranges from cold storage in nutrient media to treatment with aldehydes, antibiotics, or β -propiolactone to ethylene oxide and irradiation [3, 6]. Harsh chemical disinfection (ie, high concentrations of antibiotics, aldehydes, or β -propiolactone) and irradiation have been shown to reduce allograft durability [4, 6]. Homografts prepared by various gentle methods (ie, low-dose antibiotics) appear to have durability exceeding porcine, but perhaps less than mechanical valves [7-9]. Currently, homografts are disinfected using lower concentrations of antibiotics followed either by cryopreservation or storage of the valve in cold (4°C) nutrient media. There remains a paucity of data assessing the effects of procurement and processing on the morphologic integrity of the cryopreserved valve leaflets.

Current harvesting protocols are based on the premise that cellular viability enhances allograft durability [2, 10-16]. All valves harvested have an obligatory period of warm ischemic time from the death of the donor to immersion of the valve in cold storage solution. This obligatory warm ischemic time has been shown to affect matrix cell viability, but the time-dependent injury response has not been well characterized. Historically, valves have been harvested up to 72 hours after donor death. Most centers limit the warm ischemic time to less

Also included is the expected durability of the xenograft valves (Spampinato and associates [5]).

than 24 hours, whereas others severely restrict harvest to only virtual beating heart donors.

The purpose of this study was to quantitatively characterize the combined consequences of variable warm ischemic injury, antibiotic disinfection, cryopreservation, and thawing on human leaflet matrix cell morphology using transmission electron microscopy.

Material and Methods

Study Design

Twenty-five human cryopreserved aortic and pulmonic valves with warm ischemic times ranging from 0 minutes to 20 hours were obtained (LifeNet Transplant Services, Virginia Beach, VA) and studied using transmission electron microscopy to characterize the effects of harvesting, antibiotic disinfection, and cryopreservation on leaflet matrix cell ultrastructure. Valves were acquired by means of a standard clinical procurement and cryopreservation protocol [17]. Homograft valves selected for study were rejected for transplantation for the following reasons: (1) positive bacterial cultures (18/25 valves); (2) thickened semilunar cusps or atheromatous plaques (3/25 valves); (3) technical error during valve harvest (3/25 valves); and (4) annular hematoma (1/25 valves). The valves were divided into seven groups on the basis of warm ischemic time: group 1, 0 minutes; group 2, 0 to 1 hour; group 3, 1 to 2 hours; group 4, 2 to 8 hours; group 5, 8 to 12 hours; group 6, 12 to 16 hours; and group 7, 16 to 20 hours. Two leaflets from each valve were randomly selected for study using standard transmission electron microscopic methods.

Valve Procurement and Preservation

All the valves were aseptically procured in an operating room and cryopreserved by LifeNet. The warm ischemic time from each valve was recorded and the valve transported (4°C) in either RPMI 1640 nutrient media, 0.9% saline solution, or lactated Ringer's to the tissue bank for processing [17]. Each homograft was cultured, excess myocardium and fat were removed, and the internal valve

diameter was determined. Subsequently, the homograft was disinfected in RPMI 1640 nutrient media-antibiotic solution (cefotaxime, 240 µg/mL medium; lincomycin, 120 µg/mL medium; polymyxin B, 100 µg/mL medium; and vancomycin, 50 µg/mL medium) at 4°C for 24 hours. The homografts were then cryopreserved (1°C per minute, 10% dimethyl sulfoxide) and stored in vapor liquid nitrogen (−150°C to −190°C). The homografts were initially thawed by immersion of the storage packet in a 40°C water bath for 10 minutes with subsequent stepwise dilution of the dimethyl sulfoxide cryoprotectant using increasing volumes of fresh RPMI 1640 nutrient media (dimethyl sulfoxide concentrations, 7.5%, 5.0%, 2.5%, and 0.0%). Two semilunar cusps from each valve were fixed using 1% glutaraldehyde + 4% formaldehyde in 0.1 mol/L phosphate buffer (pH 7.4).

Transmission Electron Microscopy

After fixation, each cusp was cut from the free edge to the base and embedded in epoxy resin. To ensure that the cells observed were representative of the population of cells from each leaflet, multiple thin sections from each tissue block were cut, and one thin section from each valve leaflet was randomly selected for morphologic observation. Transmission electron microscopic studies (80 kV; JEOL 100 CX transmission electron microscope, Tokyo, Japan) were conducted using standard methods [18]. The first ten cells observed in each thin section were photographed (20 photomicrographs per valve), and the extent of cellular injury was assessed using the following criteria: (1) reversible injury (cytoplasmic edema, dilation of the endoplasmic reticulum, mitochondrial swelling) and (2) irreversible injury (mitochondrial flocculent densities, karyolysis, and disruption of the plasma membrane).

Statistical Analysis

For this study, 528 photomicrographs were analyzed. A spreadsheet containing the valve identification and the results of our analysis was constructed (Quattro Pro 3.0, Borland, Santa Cruz, CA). These data were cross-tabulated, and the resulting contingency table was analyzed for a possible linear association between time and the number (percentage) of damaged cells. A Cochran-Mantel-Haenszel χ^2 test (PC-SAS PROC.FREQ; SAS Institute, Cary, NC) was used to identify a linear association between the rows and columns of the contingency table.

Results

Fibroblasts and myofibroblasts are the predominant cell components of the leaflet matrix [19]. Endothelial cells were occasionally observed; however, they appear to be more susceptible to the effects of warm ischemia (Fig 2). Quantitative studies of leaflet collagen bundle crimp [20] and proteoglycans were not addressed in this study. A gradual increase in the number of matrix cells demonstrating morphological evidence of cellular injury with increasing duration of warm ischemia was observed (Table 1; Fig 3). After 12 hours of warm ischemia, virtually two-thirds of

Fig 2. Irreversibly injured endothelial cell observed in a homograft exposed to 6 hours of warm ischemia, illustrating the sensitivity of this cell type to ischemic injury. Note the presence of karyolysis (short arrow) and loss of plasma membrane integrity (long arrow) (compare with Fig 4). (Uranyl acetate and lead citrate stain; $\times 5,400$ before 35% reduction.)

the leaflet matrix cells were morphologically unaltered (Fig 4). However, 20 hours of warm ischemia resulted in 80% of the cell population demonstrating evidence of cellular injury (Figs 5, 6). For the first 12 hours, injury was predominantly reversible with a positive correlation between reversible cellular injury and increasing warm ischemic time ($p < 0.0001$). Thereafter, irreversible injury was noted in an increasing proportion of cells (ie, 2.7% at 12 hours up to 40% at 20 hours). No irreversible injury was observed in any cells exposed to 1 hour or less of warm ischemia (ie, beating heart donors) followed by standard cryopreservation processing. There was a gradual increase in the number of irreversibly injured cells between 1 and 12 hours of warm ischemia; however, greater than 95% of cells were free of irreversible injury. A rapid increase in the number of irreversibly injured cells was noted when harvest-related warm ischemic times increased from 12 to 20 hours ($p < 0.001$). After 20 hours of warm ischemia 80% of the matrix cells demonstrated evidence of cellular injury (40% reversible, 40% irreversible). The alteration of matrix cell ultrastructural morphol-

Fig 3. Percentage of cells observed in each category of cellular injury. X-axis groups represent the various warm ischemic intervals. Using a Cochran-Mantel-Haenszel trend analysis a positive correlation exists ($*p < 0.0001$) for reversible injury through the first 12 hours of warm ischemic time with a positive correlation ($**p < 0.001$) between 12 and 20 hours of warm ischemia for irreversible cellular injury.

ogy was observed in the following sequence: (1) dilation of endoplasmic reticulum; (2) cytoplasmic edema; (3) mitochondrial swelling; (4) presence of mitochondrial flocculent densities (ie, small, irregularly shaped electron-dense particles); (5) karyolysis; and (6) plasma membrane disruption.

Comment

The results of this study quantitatively describe the ultrastructural changes associated with variable warm ischemic injury followed by antibiotic disinfection and cryopreservation to leaflet matrix cells of human cryopreserved homograft valves. Our findings demonstrate a gradual increase in reversible cellular injury through the first 12 hours of warm ischemia; however, after 20 hours of warm ischemia, 80% of the matrix cells demonstrated morphologic evidence for either reversible or irreversible cell injury. Remarkably, these data further demonstrate little irreversible damage to the leaflet matrix cells when processing is preceded by less than 12 hours of harvest-

Table 1. Percentage of Reversible and Irreversible Cellular Injury in Cryopreserved Human Valves Processed for Use as Homografts

Result	0 Minutes	0-1 Hour	1-2 Hours	2-8 Hours	8-12 Hours	12-16 Hours	16-20 Hours

Fig 4. Representative micrograph depicts the ultrastructural features of an uninjured leaflet fibroblast after 6 hours of warm ischemia. Note the appearance of the nucleus (euchromatin, heterochromatin), mitochondria (long arrow), endoplasmic reticulum (short arrow), and cytoplasmic density. (Uranyl acetate and lead citrate stain; $\times 4,350$ before 35% reduction.)

Fig 6. Higher magnification view of the cell depicted in Figure 4, demonstrating flocculent densities (short arrow) and dilation of endoplasmic reticulum (long arrow) after 20 hours of warm ischemia. (Uranyl acetate and lead citrate stain; $\times 10,500$ before 35% reduction.)

related ischemia; however, an additional 8 hours of warm ischemia greatly increases the number of cells that underwent irreversible cellular injury. Valves harvested with relatively short warm ischemic times (12 hours or less) contain a population of matrix cells in which the majority are morphologically unaltered and thus presumably will be viable after transplantation. The exact role of these fibroblasts in promoting homograft valve durability is currently speculative; it has been suggested that viable fibroblasts may facilitate the active renewal of extracellular components depleted as a consequence of harvesting, processing, valve implantation, and the dynamic leaflet motion during the cardiac cycle. Alternatively, the presence of viable leaflet fibroblasts may simply reflect gentle

preservation techniques and have little direct impact on the long-term durability of homografts.

Current harvesting and cryopreservation protocols are based on the premise that leaflet fibroblast viability enhances valve durability [2, 10-16]. Although this hypothesis has yet to be proved, this premise has gained acceptance by comparison with studies demonstrating the reduced durability of homografts processed by methods known to be toxic to leaflet matrix cells [4, 6]. Early attempts at increasing the shelf-life of banked homografts involved harsh preservation methods such as lyophilization, irradiation, and aldehyde pretreatment. The durability of homografts processed by these harsh methods is clearly inferior to that attained with present-day techniques, because 62% and 95% of patients required reoperation within 10 and 20 years of implantation, respectively [4]. In comparison, a 95% actuarial freedom from valve failure at 4 years and 92% at 10 years have been reported for cryopreserved homograft valves placed in the aortic position in adults [2]. Cold wet-stored homografts as reported by Barratt-Boyes and others (ie, a gentle technique with presumably low cellular viability) attain an actuarial freedom from valve replacement of 95%, 78%, and 42% after 5, 10, and 14 years of implantation, respectively [3]. The Brisbane experience with cold wet-stored homografts is similar, with 58% freedom from reoperation at 15 years [12]. Cryopreserved valves demonstrate a moderate advantage in terms of durability compared with cold wet-stored valves with a moderate increase in durability compared with porcine aortic valve xenografts in similar patient populations [7]. All homograft valves, regardless of processing and storage methods, demonstrate increased durability and performance in the right ventricular outflow tract as compared with xenograft valves [7, 21-23].

Harvest-associated warm ischemia may be a critical

Fig 5. Severely injured leaflet fibroblast after 20 hours of warm ischemia, demonstrating extensive dilation of endoplasmic reticulum and mitochondrial flocculent densities. (Uranyl acetate and lead citrate stain; $\times 5,400$ before 35% reduction.)

determinant of fibroblast viability. Previous laboratory studies in which porcine aortic valves were harvested and exposed to variable periods of warm ischemia demonstrated a resilience by leaflet fibroblasts to the effects of warm ischemic injury for more than 24 hours [19] when studied before antibiotic disinfection and cryopreservation (ie, analogous to the time of cadaveric harvest-related ischemia). However, after 24 hours of warm ischemia a marked increase in the number of irreversibly injured cells was observed. A positive correlation between increasing warm ischemic time and irreversible cellular injury was demonstrated through 36 hours of warm ischemia. In the present study of human cryopreserved valves, our findings indicate the window of minimal warm ischemic injury is shorter (ie, 12 hours) before there is a marked increase in the number of irreversibly injured cells in leaflet tissue that has been harvested, processed, cryopreserved, and thawed in a manner analogous to current clinical protocols. This observation suggests that an additional reduction in the number of viable leaflet fibroblasts occurs when cadaveric harvest ischemia is followed by antibiotic disinfection, cryopreservation, and thawing. The animal studies are an important complement to understanding these human results, because the limited availability of donor tissue mandates full processing and clinical use of all human valves except for those found to be nontransplantable. Thus a control series for human valves that have only experienced cadaveric harvest ischemia is not available in this country.

The mechanism that renders the matrix cells susceptible to destruction may be related to depletion of high-energy phosphate intermediates during the warm ischemic interval. In an analysis of human cryopreserved valves processed for use as homografts, adenosine triphosphate levels decreased from 0.127 nmol/mg protein after 2 hours of warm ischemia to complete depletion of adenosine triphosphate after 13 hours of warm ischemia [24]. Significant reductions in adenosine triphosphate levels have also been observed in porcine aortic valves after brief periods of warm ischemia, antibiotic disinfection, and cryopreservation [25]. Furthermore, as the warm ischemic interval is increased, reductions in the levels of other adenine nucleotides (ie, adenosine diphosphate and adenosine monophosphate) occurs [26]. Accumulation of lactate in valvular tissue has been measured after 2 hours of warm ischemia, suggesting that around this time, ischemic leaflet cells have converted from aerobic to anaerobic metabolism [27]. Teleologically, cellular injury should progressively increase as metabolic reserves are further depleted during subsequent processing steps (ie, antibiotic disinfection, cryopreservation, and thawing) even if these steps are by themselves not toxic. Our morphologic observations in clinical human cryopreserved aortic homografts support these biochemical findings. Within relatively short periods of warm ischemia (1 to 12 hours), we observed evidence of reversible cellular injury (ie, cytoplasmic and mitochondrial edema, dilation of the endoplasmic reticulum). However, marked morphological evidence of irreversible cellular injury (ie, mitochondrial flocculent densities, karyolysis, plasma

membrane disruption) was not observed until after 12 hours of warm ischemia. These findings suggest that periods of warm ischemia less than 12 hours may represent the optimal window for valve procurement.

This study demonstrates that after 20 hours of warm ischemia and subsequent disinfection and cryopreservation 40% of the matrix cells in cryopreserved valves have been irreversibly injured. Morphologic criteria for reversible cellular injury (ie, cytoplasmic edema, dilated endoplasmic reticulum, swelling of the mitochondria) represent observations consistent with an inability of the cells to maintain osmotic gradients. With restoration of the metabolic reserves it is expected that these findings may regress. The markers of irreversible cellular injury (ie, mitochondrial flocculent densities, karyolysis, plasma membrane disruption) represent extensive cellular destruction with no chance of salvage. Mitochondrial flocculent densities, which are electron-dense irregularly shaped particles composed of calcium and phosphate found within the mitochondria matrix, correspond to the biochemical uncoupling of oxidative phosphorylation. Their presence may signal irreversible mitochondrial damage and severe depletion of intracellular adenosine triphosphate.

Results of this morphologic study demonstrate a marked increase in matrix cell irreversible injury after harvest-related warm ischemia greater than 12 hours in human allografts processed as clinical quality homograft valves. Previously, worldwide harvesting protocols allowed widely variable cadaveric harvests up to 72 hours postmortem, but currently, most restrict harvest to within 24 hours. If fibroblast viability is a significant determinant of homograft durability and performance, then warm ischemic time associated with valve procurement should be restricted to 12 hours or less unless modifications of processing methods can be implemented that reverse the progression of injury. Limiting harvests to beating heart donors is probably too restrictive and is not supported by our data. Unlike myocardial cells, fibroblasts are remarkably resilient and do not die within minutes after the onset of ischemia. Minimal cellular damage observed after short periods of cadaveric ischemia, cold antibiotic disinfection, and cryopreservation is quite impressive. Intuitively, one would expect negative effects of such processing; cryopreservation, as currently performed, is a standardized method extraordinarily effective in preserving the viability of previously uninjured valve leaflet cells. Cardiac surgeons should understand the implications of preprocessing warm ischemia and be aware of that time interval when selecting a cryopreserved homograft for transplantation, especially when prolonged durability is an issue for a specific patient. Currently our findings support three (conceptual) categories of cryopreserved homograft valves: (1) beating heart or virtual beating heart donors (less than 2 hours of warm ischemia); (2) short cadaveric harvest ischemia (2 to 12 hours); and (3) prolonged cadaveric ischemia (>12 hours but $\leq$ 24 hours). The matrix cell population in valves harvested more than 24 hours after donor death are almost certainly either nonviable or irreversibly injured, especially once exposed

to the rigors of preimplantation processing and transplantation.

Grant support was provided by The American Heart Association (Capital Affiliate), and LifeNet, Inc. Research funding for Dr Crescenzo was supported by a National Research Council Fellowship. The cryopreserved valves were provided by LifeNet, Inc.

DISCUSSION

MR ENDRE BODNAR (Pinner, United Kingdom): I would like to congratulate Dr Crescenzo and associates. I hope that this excellent report will be published and quoted in relevant publications for many years to come because it clarifies a number of problematic issues. I would like to make a few comments.

First of all, this report seemed to prove what we have been believing for some time, that all of those homografts that have been implanted over the past 25 years were nonviable because they were harvested from cadavers 24 to 72 hours after death. One may conclude this from Crescenzo and associates' data.

The second thing I would like to comment on is that it may be a mistake to equate cryopreservation with viability. The Mark O'Brien series that you have used here as an example was a

mortuary series. Therefore, in light of your results, they were cryopreserved but nonviable valves. We presented to this Society a couple of years ago results obtained in London over a 20-year period in which there was no difference in clinical performance whether the homografts were believed to be viable or not.

As far as fibroblast viability is concerned, I would like to note that it does not mean that the valve is normal. First of all, a normal valve has endothelium, and fibroblasts do not produce endothelium. Neither do they produce elastin or collagen. They produce only procollagen, and a normal extracellular environment is necessary to turn it into collagen. The so-called viable valves are not normal, and there is a question as to whether the life of a fibroblast will extend the life of the homograft.

Finally, with a view to this, there may be a new evaluation of the truly viable valves. They may be much more antigenic than those homografts that we have been working with over the past 25 years, as acute rejection was a totally unknown complication of homograft insertion until these truly and highly viable valves arrived. So when you are proposing that the best valve should be given to the best patient, I would raise the question, which is the best valve? I am not sure that the most viable is the best.

DR CRESCENZO: Thank you very much for your comments. I would like to address several points in response to your remarks.

First, endothelial cells have never been shown to be important in terms of valve durability. In fact, preservation of endothelial cells may reduce valve durability by an immunologic mediated response. It has been shown that the immunologic reaction is a result of class I antigens expressed on the surface of the endothelial cells.

As far as our statements concerning the different categories of cryopreserved valves, we still have not been able to fully elucidate the exact role of the fibroblast in promoting valve durability. We do know that cryopreservation has been shown to preserve cellular viability; however, what may be more important in terms of valve durability is that cryopreservation causes less damage to the acellular components, and this is the reason that cryopreserved valves perform better than the harsh preservation series published by the Mayo Clinic.

DR PETER K. SMITH (Durham, NC): How would you handle the bias that is introduced into your data by the fact that such a large proportion of the valves were rejected because of positive cultures? We all understand that they have been warm ischemic in a medium that is conducive to this. To what extent do your data support your conclusions even in the remaining 8 or so that were not infected?

DR CRESCENZO: Dr Smith, thank you very much for your comments as well. This very question has been raised by members of our research team. The morphologic observations reported in this study were performed on human cryopreserved valves that were processed on line in a commercial distribution center. These valves were later rejected for transplantation because of technical reasons such as positive bacterial cultures. These were "technical" infections by virtue of positive surveillance cultures—not invasive infections causing thickened cusps, for example. If we assume a worse-case scenario, our data would be overreporting cellular injury, and I think you would agree that valves with warm ischemic times of less than 12 hours had remarkably little injury.

DR FLAVIAN M. LUPINETTI (Ann Arbor, MI): I enjoyed your report very much. I think it is very important to attempt to quantitate the quality of "viability," which is sometimes referred to rather loosely. But I wonder whether your methods really determine fibroblast viability as opposed to cell death; they may not be opposite sides of the same coin. Do you have any data that relate your histologic grading to proline uptake or autoradiography or some other more affirmative line of evidence that would indicate cellular viability?

DR CRESCENZO: The proline and inulin uptake studies have been done at Old Dominion University by Dr Wolfenbarger. Our morphologic observations correlate with his findings. Recently, our laboratory has been able to culture fibroblasts in porcine heart valves with warm ischemic time as long as 48 hours. We are currently looking at whether these fibroblasts can secrete collagen in a normal fashion. Our preliminary results demonstrate that fibroblasts will proliferate in cell culture, but we still do not know if these cells will function normally.

Warm Blood Cardioplegia: Superior Protection After Acute Myocardial Ischemia

W. Morris Brown III, MD, John L. Jay, MD, John Parker Gott, MD,

Carlyle Fraser Heart Center, Crawford Long Hospital of Emory University, Atlanta, Georgia

Three myocardial protection techniques were studied in a canine model of acute myocardial ischemia with subsequent revascularization. Eighteen animals were randomly assigned to one of three treatment regimens: cold oxygenated crystalloid cardioplegia (CC), cold blood cardioplegia with modified reperfusate (CB), and continuous aerobic warm blood cardioplegia (WB) ($n = 6$ per group). Systemic hypothermic cardiopulmonary bypass (28°C), antegrade arrest, and intermittent retrograde and antegrade delivery were used for the CC and CB groups. Systemic normothermic cardiopulmonary bypass, antegrade arrest, and continuous retrograde delivery were used for the WB group. Fifteen minutes of warm global ischemia was followed by occlusion of the left anterior descending coronary artery (15-minute duration) and simultaneous initiation of cardioplegic arrest (60-minute duration) to simulate clinical revascularization. After reperfusion, the animals were separated from cardiopulmonary bypass. Myocardial function, electrocardiogram, myocardial energetics, water content, histopathology, and defibrillation requirements were compared between

groups. There was no significant difference in maximum elastance, myocardial oxygen consumption, myocardial edema, or histopathologic evidence of injury between groups. However, overall ventricular function, assessed by the slope of the preload recruitable stroke work relationship, was significantly better for the WB group ($p = 0.04$) (WB, 73 ± 9 ; CB, 56 ± 7 ; CC, 47 ± 5). Diastolic function as assessed by the slope of the stress-strain relationship was significantly worse overall for the cold groups ($p = 0.001$) (WB, 20 ± 2.2 ; CB, 39 ± 1.3 ; CC, 37 ± 3.1). Myocardial injury as assessed by ST segment elevation (millimeters) was less for the WB group ($p = 0.03$) (WB, 0.4 ± 0.3 ; CB, 1.7 ± 0.2 ; CC, 1.6 ± 0.7). Counter-shocks necessary to restore sinus rhythm after cross-clamp removal were fewer in the WB group ($p = 0.03$) (WB, 0.8 ± 0.3 ; CB, 4.0 ± 1.2 ; CC, 5.5 ± 1.5). In this model of acute global myocardial ischemia, continuous aerobic warm blood cardioplegia has important advantages over two widely used clinical hypothermic protection techniques.

(*Ann Thorac Surg* 1993;55:32-42)

Modern hypothermic cardioplegic myocardial protection techniques as practiced by the majority of cardiac surgeons yield excellent functional results. Most cardiac operations are carried out well within the bounds of safe limits of these techniques. There are certain important subsets of patients, however, that stretch these margins of safety. Patients with acute myocardial ischemia, those requiring extended cardiac arrest time for repair of complex problems, and patients with minimal myocardial functional reserve are particular challenges to existing hypothermic ischemic cardioplegic arrest techniques.

A new myocardial protection technique that uses aerobic warm blood cardioplegia, developed by surgeons at the University of Toronto, has shown promise in recent clinical studies of these problem patients [1-3]. To assess quantitatively the functional results with this new technique,

a comparison was made between aerobic warm blood cardioplegia and two clinical state-of-the-art cold cardioplegic techniques in a canine model of acute myocardial ischemia. Experimental end points included assessments of cardiac mechanics, cardiac energetics, myocardial edema, and histopathologic and electrocardiographic changes.

Material and Methods

Eighteen *Dirofilaria*-free adult mongrel dogs with body masses ranging from 23 to 32 kg were studied in a right heart bypass model of acute myocardial ischemia with simulated revascularization. All animals were premedicated with morphine sulfate (4 mg/kg) subcutaneously. Anesthesia was induced with intravenous administration of sodium pentobarbital (20 mg/kg) and maintained with intermittent boluses (3 mg/kg). The animals were endotracheally intubated and placed on a volume ventilator. Femoral artery pressure was monitored. Limb leads were placed for recording the electrocardiogram. A median sternotomy allowed cannulation of the left subclavian artery for inflow from the cardiopulmonary bypass (CPB) circuit. Venous return to the pump was through bicaval

Presented at the Twenty-eighth Annual Meeting of The Society of Thoracic Surgeons, Orlando, FL, Feb 3-5, 1992.

cannulation. The animals were initially placed on normothermic total CPB. The azygos vein was ligated. An ascending aortic cardioplegia delivery cannula was placed and secured.

Global myocardial ischemia was then initiated by cross-clamping the ascending aorta to eliminate coronary arterial flow (Fig 1). Warm myocardial ischemia was maintained for 15 minutes. During this time, the left ventricle was passively vented through the apex. The left anterior descending coronary artery (LAD) was mobilized and an encircling tourniquet placed just distal to the first septal perforator. At this point, one of the three myocardial

protection regimens was initiated (Table 1). If the animal received a cold cardioplegic technique (cold blood cardioplegia [CB], cold crystalloid cardioplegia [CC]), systemic cooling to 28°C was initiated. The group given warm blood cardioplegia (WB) had maintenance of systemic normothermia throughout. The LAD tourniquet was released 15 minutes after initiation of the cardioplegic regimen in each group, simulating surgical revascularization.

During cardiac arrest, the tricuspid valve was rendered incompetent, and a right atrial drainage line was placed to collect coronary sinus and thebesian effluent. During the subsequent working phase, this flow was returned to the pump and quantitated by electromagnetic flowmetry and intermittently sampled for oximetric analysis. Also during the arrest phase, the left ventricle was instrumented for pressure-volume studies with a high-fidelity micromanometer and three pairs of orthogonally oriented endocardial-surface ultrasonic pulse transit crystals [4].

The animals that had been systemically cooled were rewarmed to systemic normothermia. The cross-clamp was removed 75 minutes after initial placement. The heart was reperfused at a mean aortic pressure of 50 mm Hg for 2 minutes, after which the pressure was raised to 70 mm Hg where it was maintained for the remainder of the experiment. Direct-current defibrillation was ultimately successful for those hearts that did not resume a spontaneous organized rhythm. Boluses of lidocaine hydrochloride (1 mg/kg) were administered to all animals after two unsuccessful defibrillation attempts. Serum po-

Table 1. Characteristics of the Three Myocardial Protection Regimens

Group	Induction Dose		Induction Solution	Maintenance Dose	Maintenance Solution	Terminal Reperfusate	Systemic Temperature (°C)	Topical Cooling
	Antegrade	Retrograde						
CC	20 mL/kg, 4°C	10 mL/kg, 4°C	1 L solution: 20 mEq/L HCO ₃ ⁻ ; D ₅ W, 3 mL/L; KCl, 20 mEq/L; Na, 141 mEq/L; Mg, 3 mEq/L; Cl, 98 mEq/L; Acetate, 27 mEq/L; Phosphate, 1 mEq/L; Gluconate, 23 mEq/L; pH, 7.4	15 mL/kg, intermittent (q 15 min), antegrade	Same solution	No	28	Yes
CB	20 mL/kg, 4°C	10 mL/kg, 4°C	1 part crystalloid solution: D ₅ ¼ NS, 750 mL; KCl, 80 mEq/L; THAM, 200 mL; CPD, 200 mL; 4 parts blood	15 mL/kg, intermittent (q 15 min), antegrade	1 part same solution except KCl, 20 mEq/L; 4 parts blood	Yes ^a	28	Yes
WB	20 mL/kg, 37°C	Continuous, 37°C, CSP-40 mm Hg	1 part crystalloid solution: D ₅ W, 1 L; KCl, 100 mEq/L; Mg, 18 mEq/L; THAM, 40 mL; CPD, 20 mL; 4 parts blood	Continuous, retrograde	1 part same solution except KCl, 40 mEq/L; 4 parts blood	No	37	No

^a The terminal reperfusate was given as an antegrade dose, 15 mL/kg, just before cross-clamp removal. The composition was as follows: D₅W, 250 mL; D₅W, 40 mL; CPD, 225 mL; THAM, 225 mL; KCl, 30 mEq/L; glutamate/aspartate solution, 250 mL (2.02 g aspartate + 2.20 g glutamate per liter of D₅W).

CB = cold blood cardioplegia; CC = cold crystalloid cardioplegia; CPD = citrate-phosphate-dextrose; CSP = coronary sinus pressure; D₅W = 5% dextrose in water; D₅¼ NS = 5% dextrose in 0.25% normal saline solution; THAM = trihydroxymethylaminomethane; WB = warm blood cardioplegia.

tassium concentrations were maintained between 3.5 and 5.5 mmol/L (3.5 and 5.5 mEq/L) throughout the protocol.

For 20 minutes after cross-clamp removal, the hearts were kept in a vented nonworking state on CPB. The left ventricular working phase was begun by infusing blood into the main pulmonary artery at $75 \text{ mL} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$. Data were gathered during 10-minute working phases at 30, 60, and 90 minutes after cross-clamp removal. Between these data collection periods, the animals were kept on CPB.

All animals received humane care in compliance with the "Principles of Laboratory Animal Care" formulated by the National Society for Medical Research and the "Guide for the Care and Use of Laboratory Animals" prepared by the National Academy of Sciences and published by the National Institutes of Health (NIH publication No. 85-23, revised 1985).

Data Acquisition and Analysis

Hemodynamic data were gathered using an analog-to-digital conversion board (Data Translation, Inc, Marlboro, MA) and processed, stored, and analyzed with a micro-processor (model 386; Intel, Houston, TX) using an interactive program developed in this laboratory (James M. Bradford, PhD; © Emory University, 1991). The system was formatted to collect 6-second recordings of 16 channels of physiologic data. Channels were sampled every 4 milliseconds with a delay between channels of 0.25 milliseconds (250 Hz per channel). The program generated pressure-volume loops from the left ventricular micromanometer and the triaxially arrayed ultrasonic crystal dimension data as previously described from this laboratory [4].

Systolic ventricular performance was evaluated by determining the slope of the maximum elastance or end-systolic pressure-volume relationship (E_{max}) from the 6-second periods of data collection acquired during varying preload conditions [4, 5]. For the computations, the program was formatted such that end-systole was defined as the point when the pressure-volume ratio was at a maximum.

Diastolic function was assessed by calculating both left ventricular midwall circumferential stress and left ventricular Lagrangian volume strain (see Appendix 1 for derivation of the formulas used to calculate these values). End-diastole was defined as the point 32 milliseconds before the time at which the slope of the left ventricular pressure curve exceeded 1. The interactive features of the program allowed visual confirmation of the validity of these points. End-diastolic points from successive cardiac cycles during a 6-second period of rapidly changing preload minimized problems with consideration of parallel viscous properties [6]. These calculated values for stress and strain were then pooled into a single set of data points for each group and analyzed by general linear modeling and analysis of covariance for the presence of a group effect.

Overall ventricular performance was quantitated and evaluated by determining the linearized Frank-Starling relationship. This preload recruitable stroke work (PRSW)

relationship was obtained by computer integration of the area within the left ventricular pressure-volume loops. The area for a given cardiac cycle was plotted against the left ventricular end-diastolic volume for that cycle. The PRSW line was obtained as a least squares regression of multiple cardiac cycles during acute variation of the preload [4, 7].

Electrocardiographic data were collected with limb leads. Lead II was calibrated for 1 mV equal to 10 mm.

Myocardial oxygen consumption (MVO_2) was calculated using the formula:

$$\text{MVO}_2 \text{ HEART} = (C_a - C_v) \times Q,$$

where Q was the coronary blood flow quantitated by electromagnetic flow probe determination of the combined coronary sinus and thebesian vein effluent, C_a was the arterial oxygen content determined from a sample drawn from the arterial line of the CPB circuit and analyzed with an oximeter that was calibrated for canine hemoglobin to determine oxygen content (model OSM3; Radiometer, Westlake, OH), and C_v was the venous oxygen content determined from a simultaneous sample drawn from the combined coronary sinus and thebesian vein effluent. Samples were drawn at 5-minute intervals after cross-clamp removal until the completion of the experiment.

The right ventricle remained in the nonworking state throughout the postreperfusion course of the experiment. An assumption was made that the nonworking right ventricular MVO_2 ($\text{MVO}_2 \text{ RV NW}$) remained constant. Another assumption was that the atria consumed oxygen in proportion to their weight and that this remained constant. This nonworking right ventricular and atrial (A) oxygen consumption was calculated during the nonworking phase immediately before each working-phase MVO_2 measurement by the formula:

$$\text{MVO}_2 \text{ RV A NW} = \text{MVO}_2 \text{ HEART} \times [(\text{RV mass} + \text{A mass})/(\text{RV mass} + \text{A mass} + \text{LV mass})],$$

where LV mass was left ventricular mass, RV mass was right ventricular mass, and A mass was the combined atrial mass determined by the postmortem weight of the ventricles and atria stripped of the valvular apparatus, great vessels, and atrioventricular fat pad. The septum remained with the left ventricle.

Left ventricular oxygen consumption ($\text{MVO}_2 \text{ LV}$) was calculated by the formula:

$$\text{MVO}_2 \text{ LV} = \text{MVO}_2 \text{ HEART} - \text{MVO}_2 \text{ RV A NW}.$$

The $\text{MVO}_2 \text{ LV}$ was then normalized to 100 g of left ventricular mass:

$$\text{MVO}_2 \text{ NORMAL} = [\text{MVO}_2 \text{ LV}/\text{LV mass}] \times 100.$$

Normalized values were compared between groups in both the working and nonworking phases.

Myocardial water content was determined from samples of the left ventricle taken immediately after death, weighed, and placed in an oven for desiccation. The

samples were weighed daily until a constant weight was obtained for 2 days. The percent water content of the tissue was determined by the equation:

$$\text{Tissue \% water content} = \frac{[(\text{wet weight} - \text{dry weight})/\text{wet weight}] \times 100}{1}$$

Histologic examination was performed on transmural sections of the left ventricle taken from the LAD and circumflex coronary artery areas away from areas of instrumentation. These were then fixed in 10% buffered formalin. Sections were stained with hematoxylin and eosin and examined by a pathologist. Microscopic examination was carried out using high-power (40× objective, 10× ocular) fields. Each field examined was scored yes or no for the presence of one of the following markers of myocyte damage: contraction band necrosis, hyper eosinophilia, or smudging of the myofibrils with loss of cytoplasmic detail (poorly visible cross striations). The score for a particular sample was the ratio of fields exhibiting at least one of the markers of damage to the total number of fields examined (range of fields examined, 73 to 134). Specimens were also evaluated for presence and severity of intramyocardial hemorrhage for both the LAD and circumflex regions. The scoring system was as follows: 0 = no evidence of intramyocardial hemorrhage; 1 = one to three foci of hemorrhage in either the LAD or circumflex area only; 2 = one to three foci of hemorrhage in both regions; 3 = extensive hemorrhage in one region, and 4 = extensive hemorrhage in both regions.

Statistical Analysis

Statistical analyses were carried out on a microprocessor using proprietary software (RS1, BBN Software Products Corp; BMDP, BMDP Statistical Software, Inc) with the advice of a statistician (R. S. Clark, PhD, Emory University). Myocardial water content, histologic injury scores, and defibrillation requirements were compared using one-way analysis of variance. Intramyocardial hemorrhage scores were compared using χ^2 testing. Diastolic stress-strain data were compared by analysis of covariance. All other comparisons were done by analysis of variance with repeated measures. All values are expressed as the mean $\pm$ the standard error of the mean. Significant differences were said to exist when the *p* value was less than 0.05.

Results

All animals were tapered from CPB. In general, the WB-protected animals had fewer rhythm disturbances and were separated more readily from bypass. The mean arterial pressure was maintained at 70 mm Hg (± 3 mm Hg), and the average heart rate was 166 beats per minute at the time of data collection. Left ventricular distention was assiduously avoided, and end-diastolic pressure did not exceed 15 mm Hg in any animal.

Ventricular systolic performance, assessed using the maximum elastance relationship ($E_{\max}$), showed no significant difference between groups (30 minutes—WB, 8.5

Fig 2. Typical pressure-volume loops from each group during varying preload conditions. Linear regression fitting of the maximum elastance relation ($E_{\max}$) is shown. Note also the steeper slope during diastolic filling characteristic of the cold protection groups compared with the more compliant aerobic warm protection group. (B = y-intercept; CB = cold blood cardioplegia; CC = cold crystalloid cardioplegia; LVP = left ventricular pressure; R = correlation coefficient; WB = warm blood cardioplegia; X off = x-intercept.)

± 1.2 ; CB, 7.1 ± 1.6 ; CC, 6.0 ± 0.9 ; 60 minutes—WB, 11.5 ± 2.3 ; CB, 10.5 ± 2.0 ; CC, 7.0 ± 1.2 ; 90 minutes—WB, 10.1 ± 1.6 ; CB, 9.3 ± 1.5 ; CC, 7.2 ± 2.0); however, the mean slope was greater for the WB group at all times (Figs 2, 3). The mean correlation coefficient for the $E_{\max}$ linear regressions was 0.98.

Analysis of diastolic function, as evaluated by the stress-strain relationship, revealed significantly diminished ventricular compliance in the cold groups. The slope of the stress-strain relationship was significantly lower in the WB group compared with the cold groups ($p = 0.001$) (WB, 20 ± 2.2 ; CB, 39 ± 1.3 ; CC, 37 ± 3.1) (Figs 4, 5).

Overall left ventricular performance, as assessed by the

PRSW relationship, was significantly better for the WB group at all times ($p = 0.04$) (Fig 6). Also, the CB group was significantly better than the CC group overall ($p = 0.04$) (CB, 66 ± 7 ; CC, 49 ± 7). There was improvement in overall ventricular function for the CB group over time ($p = 0.008$) (30 minutes, 56 ± 6 ; 90 minutes, 73 ± 9). The WB and CC groups, however, did not demonstrate this time effect (WB: 30 minutes, 73 ± 9 ; 90 minutes, 82 ± 7 ; CC: 30 minutes 47 ± 5 ; 90 minutes, 55 ± 5 ; $p =$ not significant). The mean correlation coefficient for the PRSW relationship was 0.98.

Electrocardiographic analysis demonstrated significant ST segment elevation that persisted across time in both cold cardioplegic groups ($p = 0.03$) (Fig 7).

Myocardial oxygen consumption was used to assess cardiac energetics. There were no significant differences in MVO_2 between groups either early after cross-clamp removal during the nonworking phase or over time (Fig 8).

There were also no significant differences in the postoperative percent myocardial water content between groups (WB, $77\% \pm 2\%$; CB, $77\% \pm 1\%$; CC, $78\% \pm 1\%$).

Histologic examination showed presence of myocardial damage in all three treatment groups; however, there was

Fig 3. Comparison of systolic myocardial performance using the mean slopes and intercepts of the maximum elastance relationship (E_{max}) for each group during the working phase 30, 60, and 90 minutes after cross-clamp removal. (CB = cold blood cardioplegia; CC = cold crystalloid cardioplegia; NS = not significant at the $p < 0.05$ level; WB = warm blood cardioplegia.)

Fig 4. Pooled diastolic stress-strain raw data with linear regression fitting for each group during varying preload conditions (stress expressed as dynes $\times 10^3/\text{cm}^2$). (CB = cold blood cardioplegia; CC = cold crystalloid cardioplegia; WB = warm blood cardioplegia.)

no significant difference in the myocardial injury score between the two regions or between the three groups (combined LAD and circumflex scores: WB, 13.7 ± 2.1 ; CB, 7.9 ± 2.1 ; CC, 14.0 ± 4.7). There was also no difference in the intramyocardial hemorrhage score between the three groups (WB, 2.8 ± 0.6 ; CB, 2.8 ± 0.4 ; CC, 3.0 ± 0.3).

The number of countershocks necessary to resume sinus rhythm after cross-clamp removal was significantly less in the WB group (WB, 0.8 ± 0.3 ; CB, 4.0 ± 1.2 ; CC, 5.5 ± 1.5 ; $p = 0.03$).

Comment

Hypothermic cardioplegic techniques have been a mainstay for intraoperative myocardial protection for most

Fig 5. Comparison of diastolic stress-strain relationship between the three groups demonstrating the significantly more compliant left ventricle after aerobic warm blood cardioplegia (wb). (cb = cold blood cardioplegia; cc = cold crystalloid cardioplegia.)

cardiac surgeons. Central to these techniques is the profound change in myocardial oxygen and substrate delivery during the cross-clamp period and the use of chemical

Fig 6. Global myocardial performance between groups quantitated by the preload recruitable stroke work relationship during the working phase 30, 60, and 90 minutes after cross-clamp removal showing significantly better overall left ventricular function with aerobic warm protection. (CB = cold blood cardioplegia; CC = cold crystalloid cardioplegia; WB = warm blood cardioplegia.)

Fig 7. Electrocardiograms from a representative animal in each group comparing ST segment changes. Electrocardiographic signs of injury are significantly less in the warm blood cardioplegia group. Data are shown as the mean $\pm$ the standard error of the mean.

electromechanical arrest and hypothermia to minimize the resultant deleterious effects on cellular metabolism, energy stores, and structure [8].

Potential limitations of cold ischemic protection are well recognized and include patients with acute injury, diminished functional reserve, and prolonged operation. A novel myocardial protection technique using continuously delivered oxygenated normothermic blood cardioplegia [1] has the potential to improve myocardial protection in these difficult subsets of patients. This warm cardioplegic technique theoretically avoids an ischemic period. The principle of cardiac operation in a motionless field is achieved with hyperkalemic electromechanical arrest. This diastolic arrest in turn reduces the myocardial energy requirements to low levels [9, 10]. These lowered energy requirements appear to be met by a continuous

Fig 8. Comparison of myocardial oxygen consumption (MVO₂) between groups 10 minutes (early), 30 minutes, 60 minutes, and 90 minutes after cross-clamp removal. There were no significant differences (NS) between groups. Data are normalized per 100 g of left ventricle (LV).

but reduced supply of oxygen and substrate from aerobic blood cardioplegia through standard antegrade or retrograde delivery systems [11]. Those enzyme-mediated cellular homeostatic mechanisms impaired by hypothermic techniques but unaffected by hyperkalemic arrest can proceed by virtue of the normothermic state [12].

Warm heart surgery was introduced clinically by Lichtenstein and colleagues [1, 2] at the University of Toronto. A consecutive series of 121 patients undergoing coronary revascularization received warm blood cardioplegia and were compared with a historical cohort of 133 patients protected with standard hypothermic techniques [2]. The patients in the aerobic warm surgical group fared significantly better judged by a number of important clinical end points. They had fewer myocardial infarctions, a decreased incidence of low cardiac output syndrome, and less need for balloon counterpulsation. More than 99% of this group returned to sinus rhythm spontaneously after cross-clamp removal compared with about 1 of every 10 patients receiving cold ischemic protection.

The Toronto surgeons [3] then reported the expanded use of the aerobic warm myocardial protection regimen to a higher-risk group including elderly patients and patients requiring emergent operation, encompassing valve operations as well as coronary revascularization. Again, the new cardioplegic technique worked well: only 3% died, 7% required intraaortic balloon pump use, and 6% had a perioperative myocardial infarct in this high-risk population.

Yau and co-workers [13] subsequently compared different flow rates and hemoglobin concentrations for continuous warm blood cardioplegia in patients and found significantly increased MVO_2 during cardioplegia and increased myocardial adenosine triphosphate levels after cross-clamp removal in the high-flow, high-hemoglobin warm group compared with other warm and cold groups. Compliance was also better in the high-flow, high-hemoglobin group, but no significant difference was found in overall or systolic ventricular performance. Notably, only antegrade delivery was used, and the warm blood cardioplegia was interrupted while the distal anastomoses were placed. These warm ischemic periods were compensated by replenishing antegrade aortic and vein graft infusions.

The early clinical trials are encouraging and do not appear to have demonstrated any major negative functional effects of the retrograde aerobic warm technique. Because improvement in the care of patients with difficult myocardial protection problems would be a real clinical advance, further investigation in this setting is worthwhile.

For the current study, a canine model was used that allowed sophisticated analyses of left ventricular myocardial protection not readily obtainable in patients. The new aerobic warm technique was compared with two commonly used cold ischemic techniques to maintain clinical relevance. Differences in timing of doses, continuity and route of delivery, temperature, and composition of solutions in this study were all done with the intent of optimizing the currently practiced clinical methodology

for each technique. For example, retrograde delivery of some cold crystalloid cardioplegia was included to minimize distribution problems, the cold blood technique included a warm/modified/enriched reperfusate, and the warm cardioplegia was given continuously throughout the cross-clamp period. Continuous retrograde maintenance delivery of cold cardioplegia was not done and could have unfairly favored the warm group, as continuous hypothermic cardioplegia may be detrimental to functional recovery [2].

In this model of acute global myocardial ischemia, two critical end points that readily translate into clinical relevance clearly favored warm blood cardioplegia over hypothermic ischemic methods. Both myocardial mechanical performance and electrocardiographic assessment of injury were significantly better in the warm protection group.

Systolic function was assessed by the time-varying elastance model. Quantification and comparison are based on the slope of this linear relationship, $E_{\max}$. This methodology has been extensively studied and validated as a correlate of myocardial contractility or systolic function over the range of physiologic preload and afterload [5]. All groups had satisfactory recovery of contractility. Although the differences were not significant, contractility in the WB group exceeded that in the CB animals, which in turn surpassed the CC group values. These relationships persisted over time.

Although ventricular diastolic properties are notoriously difficult to assess, diastolic function significantly affects overall myocardial performance [6, 8]. Stress-strain measurements allow comparison of compliance while minimizing parallel viscous properties [6]. Nevertheless, the true stress-strain correlation or measure of intrinsic stiffness remains elusive. Numerous equations have been put forth to describe the diastolic pressure-volume relationship [14, 15]. Glantz [15] extensively reviewed the general problems associated with any of the proposed isolated indices of ventricular stiffness. Less problematic is the empiric comparison of data to determine whether or not measured diastolic pressure-volume curves are shifted or different. The task then becomes a linear regression problem [15]. Individual calculated stress-strain values for all animals at each time were pooled into the three groups and linear regression analyses carried out. The cold groups had significantly higher slopes corresponding to a decreased compliance compared with the WB group. This demonstrates a requirement for higher filling pressures to achieve a given preload volume in the cold protection groups. Speculation as to the mechanism of the poor compliance in the cold groups is outside the scope of this study; however, greater myocardial edema is not suggested by the water content study, which was the same for all three groups.

Overall ventricular function was assessed by the PRSW relationship as described by Glower and associates [7]. The relationship correlates cardiac performance as measured by stroke work to end-diastolic volume under changing preload conditions and is dependent on both systolic and diastolic properties. Data from this study

Fig 9. Pressure-volume relationship, illustrating potential for the detrimental effect of impaired diastolic function on pressure-volume area. (ESPVR = end-systolic pressure-volume relationship.)

demonstrate significantly better global ventricular function in the WB group as measured by PRSW. Because there were no significant differences in ventricular systolic function between groups, this suggests that an important part of the observed overall effect may be due to differences in diastolic function between groups (Fig 9). The CB group was superior to the CC group in overall ventricular performance. It is interesting that the CB group had an intermediary position in functional result as well as in the time course of development or evolution of these techniques. It was the only group to show improvement over time. The superior function of the WB cohort was evident immediately after separation from CPB, yet it did not improve with time. Inferior function was evident immediately after separation from CPB in the CC group and did not improve over time.

Electrocardiographic analysis also strongly favored the WB-protected hearts. This supports similar findings from the clinical studies presented earlier. These data indicate that warm blood cardioplegia, in addition to its myocardial protective effect, may actually help resuscitate the acutely damaged heart.

The mechanism of this resuscitative effect is still hypothetical, but it is clear that even though depletion of high-energy phosphate compounds occurs at a much slower rate during anaerobic hypothermic arrest, in some cases it may continue until irreversible cell damage has occurred [16]. Clinical studies [13, 17] have shown superior preservation of high-energy phosphate levels and decreased lactate accumulation with continuous warm blood cardioplegia versus intermittent cold blood cardioplegia. This implies that warm blood, in addition to maintaining electromechanical arrest, continuously supplies oxygen and substrate to the heart and allows metabolic pathways to proceed with aerobic metabolism. However, no studies to date have shown repletion of high-energy phosphate compounds using continuous warm blood cardioplegia after ischemic injury, and this warrants further investigation.

Our finding of similar histologic evidence of cellular damage in all groups demonstrates that none of these protection methods totally reversed the damaging ischemic effects or eliminated the subsequent reperfusion insult in this model of global ischemia.

Myocardial oxygen consumption showed no difference between groups. It is not possible to tell from our data the WB group incurred less oxygen debt during the cross-clamp period as previously seen by Matsuura and associates [18]. Theoretically this debt could have resulted in a larger oxygen consumption in the CC and CB group during the early reperfusion period [13], but this was not seen. Alternatively, one could hypothesize that the MVC would be lower in the hearts more severely injured immediately after cross-clamp removal as the result of an inefficiency of oxygen extraction and utilization because of more severe cellular metabolic derangement. This requires further study to draw any definite conclusions.

There was also no difference in myocardial water content between the three groups. This demonstrates that continuous warm blood cardioplegia does not result in an increase in myocardial edema compared with the intermittent cold crystalloid or cold blood methods.

The WB group required fewer attempts at defibrillation after reperfusion as is seen clinically [1-3, 19]. This may be explained by the uniformity of myocardial temperature at the time of cross-clamp removal in the WB group compared with the CC and CB groups, where uneven rewarming can cause differential speed of depolarization which can result in fibrillation.

One recent study [20] reported exacerbation of acute regional ischemic injury with warm blood cardioplegia; however, this study used antegrade cardioplegic delivery exclusively, which may not deliver cardioplegia adequately to the areas of myocardium distal to major coronary stenoses. Retrograde delivery would appear to be a rational part of the warm blood technique, as it more assuredly delivers cardioplegic solution to all areas of the myocardium [21].

Avoiding ischemic injury during aortic cross-clamp is fundamentally dependent on supplying sufficient energy to meet myocardial metabolic demands [8, 22]. Electromechanical arrest alone has clearly been shown to reduce MVO_2 by 65% to 90% with hypothermia contributing another 5% to 25% [2, 9, 10]. However, even during profound (4°C) hypothermic arrest, the myocardium still requires a supply of energy to maintain basic cellular metabolic processes, ionic homeostasis, and cell membrane stability. There is ample evidence that anaerobic glycolysis is inadequate to meet these demands for extended periods [16, 23]. Furthermore, profound hypothermia impairs glycolysis and anaerobic energy utilization [22]. Current hypothermic ischemic techniques allow a variable degree of deterioration in heart function during the cross-clamp period. Although this deterioration occurs at a reduced rate, glucose and adenosine triphosphate utilization are decreased to a greater degree, resulting in a net negative energy balance [1, 24]. Anaerobic techniques may also make the heart vulnerable to reperfusion injury after aortic cross-clamp removal [2]. In a

attempt to overcome the problems of anaerobic cold arrest, Rosenkranz and colleagues [25] used normothermic induction of blood cardioplegia with intermittent cold maintenance doses. Furthermore, Teoh and associates [26] and Rosenkranz and co-workers [27] demonstrated accelerated myocardial metabolic recovery with terminal warm blood cardioplegia.

The obvious progression of this line of reasoning is that if warm *induction* and *terminal* warm cardioplegia are beneficial to myocardial recovery, warm *maintenance* of arrest is worthy of investigation. The warm technique theoretically avoids many of the potential problems associated with anaerobic cold arrest by allowing the heart to continue using oxygen and substrate for energy production and maintenance of normal cellular metabolism [1].

However, the warm technique presents some new technical problems. These relate primarily to the difficulty with visualization during coronary bypass procedures compared with the asanguineous field associated with hypothermic techniques. Excellent visibility is crucial for reliable, faultless coronary operations. Concern for this may dissuade surgeons from using this technique unless compelling scientific evidence suggests that the warm technique offers clear-cut patient benefit.

Both the clinical trials and the results from this study suggest that the warm blood technique is both safe and effective. These data suggest an advantage for warm blood cardioplegia in the setting of acute ischemia. The data do not yet support the use of warm blood in the majority of cases, but in this canine model, the results indicate that this technique may resuscitate and protect acutely ischemic myocardium significantly better than standard hypothermic regimens. This was demonstrated by improved recovery of global and diastolic myocardial function, less electrocardiographic injury, and prompt return to sinus rhythm after reperfusion. Continuous aerobic warm blood cardioplegia warrants further clinical and laboratory investigation to define the mechanisms of protection, as it appears to have the potential for an important role in cardiac surgery.

Appendix 1. Derivation of Stress and Strain Data Points

The left ventricle is modeled as a thin ellipsoidal shell with three unequal orthogonal axes. Laplace's formula for thin-walled ellipsoids was used to calculate wall stress (σ), as it has previously been shown to be the most accurate [28]. The lengths of the axes were measured by three pairs of sonomicrometer crystals placed on the endocardial surface as previously described [4]. The base-apex crystal pair (BA) was used to measure the major-axis length. The septal-free wall (SFW) and anterior-posterior (AP) crystal pairs were used to measure and calculate the minor-axis length. The minor axis (A_{mj}) was calculated as the arithmetic average of the SFW and AP lengths, as Laplace's formula assumes symmetry of the minor axis:

$$A_{mj} = (SFW + AP)/2. \quad (1)$$

Because the "base" crystal was placed epicardially, a correction factor (representing the myocardial thickness at the placement of the base crystal) of 0.3 cm was subtracted from the measured length to obtain the corrected length (BA_c):

$$BA_c = BA - 0.3 \text{ cm}. \quad (2)$$

This correction was previously found to be the average thickness of myocardium measured post mortem in the area of crystal placement in previous experiments in this laboratory.

The major axis (A_{mj}) is equal to the corrected base-apex length:

$$A_{mj} = BA_c. \quad (3)$$

The ellipsoidal shell volume (V_s), used to calculate the midwall circumferential stress, was calculated by finding the volume of the ellipsoid based on the endocardial crystals (V_i) and subtracting this from the ellipsoidal volume calculated as if the crystals were placed epicardially (V_e):

$$V_s = (V_e - V_i). \quad (4)$$

The formula for the internal ellipsoid volume is:

$$V_i = \pi/6 \times (SFW)(AP)(BA_c). \quad (5)$$

The volume of V_e must be derived by adding the average mid-circumferential wall thickness (h) to each axis length. The calculated external diameters of the SFW and AP lengths are

simply the respective length plus $2 \times h$. Along the BA axis, the wall thickness has been shown to be 55% of that in the other areas by previous studies (29). Therefore $2 \times 0.55 h$ is added to the BA_c length. Thus, the external ellipsoid volume equation is:

$$V_e = \pi/6 \times (SFW + 2h)(AP + 2h)(BA_c + 1.1 h). \quad (6)$$

The mass of the left ventricle (M), measured post mortem, is equal to the shell volume (V_s) multiplied by the specific gravity of normal myocardium:

$$M = 1.07(V_s). \quad (7)$$

By substituting equation 4 into equation 7, this becomes:

$$M = 1.07(V_e - V_i). \quad (8)$$

By substituting equations 5 and 6 into equation 8, the mid-circumferential wall thickness (h) can be iteratively determined, as all other variables are known. The average thickness for all end-diastolic points is then calculated and stored as h .

Stress (σ) is calculated using the formula of Laplace. This formula calls for major-axis and minor-axis midwall radii; therefore, one wall thickness must be added to each axis length (a diameter) and the sum divided by two. This yields the equation for minor-axis midwall radius (Mi_{mwr}):

$$Mi_{mwr} = (A_{mj} + h)/2. \quad (9)$$

Likewise the major-axis midwall radius (Mj_{mwr}) is calculated from the major-axis diameter measurement, taking into consideration that the wall thickness is only 55% of the average midwall thickness for the minor axis:

$$Mj_{mwr} = (A_{mj} + 0.55h)/2. \quad (10)$$

The radii can be substituted into the ellipsoid modification of Laplace's formula for midwall circumferential stress (σ):

$$\sigma = 1 - \frac{(Mi_{mwr})^3}{(LVP \times Mi_{mwr})/h \times [(Mj_{mwr})^2 \times (2Mi_{mwr} + h)]} \quad (11)$$

where LVP is left ventricular pressure.

Lagrangian strain (ϵ) is calculated based on an unstressed left ventricular volume (V_0), which is obtained at the end of a sustained period of vena cava occlusion allowing maximum emptying of the heart and at a time when the left ventricular pressure is equal to 0 or at a minimum. Strain (ϵ) at any end-diastolic volume (V) is:

$$\epsilon = (V - V_0)/V_0. \quad (12)$$

The midwall circumferential stress (σ) and Lagrangian strain (ϵ) were calculated for each end-diastolic time point during a 6-second period of rapidly decreasing preload.

DISCUSSION

DR WILLARD M. DAGGETT (Boston, MA): Such an elegant study with beautiful physiology is what we have come to expect from your group, Dr Brown. I have a couple of comments that relate to your study as well as other studies presented in this session and that concern the basic concept of continuous warm blood cardioplegia apart from the problems that may be related to the delivery, whether antegrade or retrograde.

My colleagues and I have just completed a study in which we

measured peak creatine kinase levels after coronary bypass procedures in three groups of patients: patients with intermittent oxygenated dilute cold blood cardioplegia, patients with continuous warm blood cardioplegia delivered antegrade, and patients with continuous warm blood cardioplegia delivered retrograde. The lowest values, and they were strikingly low, were in the group with antegrade delivery of continuous warm blood cardioplegia. The second best levels were achieved with intermittent

oxygenated dilute cold blood cardioplegia, and the worst values were with continuous retrograde delivery. We heard earlier today about the persistence of electrical and associated mechanical activity with continuous warm blood cardioplegia. I do not think that is a problem when we are delivering blood cardioplegia antegrade at arterial pressure through the grafts. It may present serious problems of distribution when delivery is retrograde through veins at low pressure.

DR BROWN: My only comment is that other investigators have shown that antegrade continuous warm blood cardioplegia in the presence of critical coronary stenoses appears to be associated with suboptimal protection. This is perhaps in part due to maldistribution to those areas of myocardium distal to the area of blockage, whereas retrograde cardioplegia appears to distribute better to these areas.

DR IRVIN B. KRUKENKAMP (Boston, MA): I also congratulate you on a fine study. I can reinforce your findings with some data my colleagues and I have recently accumulated using the pig heart in a similar model of acute occlusion of the left anterior descending coronary artery (LAD) followed by retrograde warm or cold cardioplegia. In the cold group, there was a functional deficit both globally and regionally of approximately 29% compared with 100% recovery of function in the warm group.

Measuring myocardial oxygen consumption during the cross-clamp period in our model, we obtained a control oxygen utilization of 0.85 mL per 100 g of left ventricle per minute that increased on removal of the LAD snare to 1.2 and then fell to 1 mL · 100 g⁻¹ · min⁻¹ at the end of the ischemic period before reperfusion. We consider this an oxygen utilization for repair.

Do you have any data on regional oxygen consumption or regional cardiac mechanics, as your model is really one of regional stunning and ischemia? To follow-up on Dr Daggett's comment regarding the delivery of cardioplegia by the retrograde route, there are obvious differences between dog hearts, pig hearts, and human hearts. Do you have any data in that regard?

DR BROWN: I do not have any specific data regarding comparative delivery of retrograde cardioplegia in porcine versus canine versus human hearts. Individual studies of retrograde flow and coronary venous anatomy exist for each of these species, however. We did do some regional functional studies using the regional analogue of preload recruitable stroke work. There was a fair amount of variation in the numbers, and we were not able to discern a difference either regionally within an animal or across the three groups in terms of regional stroke work because of this variability.

DR RICHARD M. ENGELMAN (Springfield, MA): In the animal study that you did, did you discover any change between warm and cold in the incidence of intraventricular conduction disturbances? You mentioned T wave abnormalities after reperfusion. I wonder if the animals behaved as humans do, which, in our hands at least, means there is an incidence of cold-induced conduction disturbance. We do not see this with the effects of reperfusion during warm protection.

DR BROWN: In our electrocardiographic analysis, we did see prolongation of the QRS complexes but did not quantitate that; however, no animal required pacing for separation from cardiopulmonary bypass.

Total Anomalous Pulmonary Venous Connection in Neonates and Young Infants: Repair in the Current Era

Adnan Cobanoglu, MD, and Victor D. Menashe, MD

Divisions of Cardiopulmonary Surgery and Pediatric Cardiology, Oregon Health Sciences University, Portland, Oregon

Total anomalous pulmonary venous connection has been one of the more challenging congenital heart defects in newborns and young infants despite improvements in surgical technique, cardiac anesthesia, neonatal myocardial preservation, and postoperative care. Since 1981, 30 patients with total anomalous pulmonary venous connection have undergone primary total correction. Mean age at operation was 28 ± 6 days and mean weight, 3.3 ± 0.7 kg. Essential features of the surgical approach in these small patients included early surgical intervention, profound hypothermia with total circulatory arrest, cardioplegic myocardial preservation, and a wide posterior anastomosis. Operative mortality was $13\% \pm 6\%$. All four deaths were in patients having emergency operation within 24 hours of the surgical consult and requiring

ventilator support preoperatively. The mean follow-up is 47 ± 7 months. There have been two late deaths, and the 7-year survival rate is $79\% \pm 8\%$. There have been two reoperations, and $91\% \pm 6\%$ of the patients are reoperation free at 7 years. Only 1 of the 24 surviving patients is symptomatic. Growth in survivors is closely monitored. The height growth percentile is less than 5% in $15\% \pm 8\%$ of survivors and the weight growth percentile, less than 5% in $17 \pm 8\%$. During the past decade, with a consistent surgical approach to neonates and infants with total anomalous pulmonary venous connection, it has been possible to achieve low early mortality, low attrition, and excellent late results.

(*Ann Thorac Surg* 1993;55:43-9)

Total anomalous pulmonary venous connection (TAPVC) is a rare congenital cardiac anomaly, seen in only 1% of patients with congenital heart disease. It is a life-threatening anomaly when present, and few patients live beyond the first year of life without surgical correction. Over the last decade, substantial improvements have been achieved in surgical technique, cardiac anesthesia, myocardial preservation, and postoperative care of patients with this disease. Despite this progress, TAPVC in neonates and young infants continues to challenge the abilities of pediatric cardiac services. Over the last 10 years at the Oregon Health Sciences University, a consistent approach to repair with early surgical intervention has been followed. The purpose of this report is to review and illustrate current results with repair of TAPVC in a regional pediatric cardiac surgery center.

Patients and Methods

Patient Selection

All patients with TAPVC referred to the University Hospital between July 1981 and July 1991 form the basis of this review. The clinical characteristics of these patients are summarized in Table 1. The mean birth weight of the patients was 3.2 ± 0.1 kg; the distribution is shown in

Figure 1. The mean age at operation was 28 ± 6 days (range, 12 hours to 15 months), and the mean weight was 3.3 ± 0.7 kg (Figs 2, 3). The infradiaphragmatic type of TAPVC was the most frequent and was seen in 17 patients (56.7%). The supracardiac type was present in 8 patients (26.7%) and the intracardiac type, in 5 (16.7%).

The mean pulmonary artery systolic pressure was 75.4 ± 2.0 mm Hg (range, 45 to 125 mm Hg) before operation in the patients who had cardiac catheterization. The most common associated cardiac anomaly was a patent foramen ovale, which kept these patients alive. Five patients had a patent ductus arteriosus that was closed at the time of cardiac repair. Two patients had pinhole ventricular septal defects.

During the earlier years, it was routine to perform cardiac catheterization soon after arrival of the patient at the neonatal intensive care unit to diagnose and delineate the exact type of problem. In later years, almost all diagnoses were made by echocardiography alone (7 patients). Fifteen patients (50%) were diagnosed as having pulmonary venous obstruction by a combination of chest roentgenograms and cardiac catheterization.

Once the diagnosis was established, all patients had early repair. In 19 patients it was possible to wait for the next scheduled operating slot, usually within 24 to 36 hours of diagnosis (urgent cases). Eleven patients had emergency procedures within 24 hours after brief periods of stabilization. Most of the earlier patients had balloon atrial septostomy, and those with intractable tachypnea

and cyanosis or congestive heart failure were sedated and treated on the ventilator.

Surgical Technique

All patients were anesthetized by a member of the cardiac anesthesia team. For the first 20 patients, the perfusion technique entailed surface cooling to 32°C followed by profound hypothermia and total circulatory arrest and subsequent rewarming on bypass. In the last few years, surface cooling has been abandoned, and slow cooling to 17° to 18°C on bypass and a period of arrest have been used. Myocardial protection was achieved by potassium-induced cold cardioplegia with injection of 200 to 300 mL of the solution at 4° to 5°C into the aortic root right at the start of circulatory arrest.

In patients with supracardiac or infradiaphragmatic connection, the heart was lifted cephalad and to the right to facilitate posterior mediastinal dissection over the pulmonary venous trunk. Long transverse incisions were made on this common pulmonary vein and on the left

Fig 2. Age at operation for total anomalous pulmonary venous connection.

atrium (Fig 4). A wide, unrestrictive anastomosis (usually greater than 2.5 cm in length) was constructed with a running suture of 6-0 or 7-0 polypropylene (Fig 5). The vertical vein was ligated and the atrial septal defect closed in all patients.

In patients with intracardiac connection, all of whom had return to the coronary sinus, the approach was through a longitudinal right atriotomy. The septum between the enlarged coronary sinus and left atrium was everted into the patent foramen ovale and widely excised (Fig 6). The foramen ovale was closed primarily in most patients; occasionally a small patch was necessary. All coronary sinus blood was diverted to the left atrium by patch closure of the coronary sinus ostium (Fig 7). Particular attention was given to insert the patch within the ostium and away from the conduction tissue, particularly around its anterior perimeter.

Data Analysis

Data analysis was performed by the Office of Research Development and Utilization, Oregon Health Sciences University. Mean values were calculated for continuous, interval-level variables. All means were reported with standard errors (mean ± 1 standard error). Inferential analysis was performed using Fisher's exact test. This test is appropriate for comparisons of two samples with di-

chotomous outcomes when sample sizes are small. Analysis of time-related events was performed using actuarial methods. Estimates were computed at 30-day intervals.

All patients who survived have been contacted or seen in the outpatient clinic within 2 months of the conclusion of this study (July 1991).

Results

The operative mortality rate was $13\% \pm 6\%$. All four deaths were associated with a low cardiac output state in patients having emergency operation and requiring intubation and ventilator support preoperatively (Figs 8, 9).

Table 2 summarizes the effect of preoperative variables on operative outcome. Presence of pulmonary venous obstruction did not affect mortality and actually was last on the list of variables examined. Important intraoperative variables included cardiopulmonary bypass time of 36 ± 10 minutes and total circulatory arrest time of 45 ± 12 minutes.

Twenty-three patients had some inotropic support postoperatively, although most received only a routine infusion of $5 \text{ g} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$ of dopamine hydrochloride for 24 to 36 hours. Eleven patients needed temporary pacing, mostly for the first 4 to 12 hours in the intensive care unit and principally for junctional rhythm. Twenty-four patients were extubated within 72 hours after operation. Two patients needed 92 hours and 116 hours of ventilatory support before extubation. All patients but these last 2 were feeding by mouth within 24 hours after

extubation. One patient had renal failure with spontaneous resolution.

Three-fourths of the patients were discharged from the hospital within 2 weeks after operation. The other 25% stayed up to 30 days. The mean follow-up is 47 ± 7 months (range, 4 to 126 months). There have been two late deaths; 1 patient died of persistent pulmonary hypertension, and the second had recurrent pulmonary venous obstruction. Actuarial survival at 7 years is $79\% \pm 8\%$ (Fig 10).

Ninety-one percent $\pm 6\%$ of the patients are free from reoperation (Fig 11). Two reoperations were performed at 3 months and 3 years, both for diffuse pulmonary venous obstruction proximal to the anastomosis. Twenty-three of the 24 patients alive are totally asymptomatic. Growth

percentiles for height and weight have been good and are summarized in Tables 3 and 4.

Comment

It is now nearly 200 years since the first description of TAPVC [1] and 40 years since the first surgical treatment [2]. This anomaly is truly a surgical disease, and medical therapy is merely supportive and preparatory to surgical correction. Because long-term medical management would be very unusual, over the last 10 years, we have taken an aggressive approach to neonates with this disease by planning early surgical intervention after a brief period of stabilization. In our experience, older patients who are seen late in life have been very rare, and our patients mostly have been neonates and a few infants up to 15 months of age. Almost all patients were seen with cyanosis, tachypnea, and tachycardia soon after birth and quite frequently required inotropic and ventilator support before operation.

Over recent years, several groups [3-6] have reported improved results with operative intervention, and the 13% operative mortality rate in the current series compares very favorably with the rates in these reports. Of note is the large number of patients in our group who would be considered in extremis before surgical intervention. All deaths in these series occurred in patients who required emergency operation and intubation in the emergency room or neonatal intensive care unit, and all deaths

Fig 10. Actuarial survival after repair of total anomalous pulmonary venous connection.

were due to persistent low cardiac output. In a series from Vanderbilt University [7], four of the five deaths also were in patients who needed preoperative ventilator support.

This experience does not show a higher risk in relation to certain types of anomalous venous connection, particularly infradiaphragmatic type, as reported by Turley and co-workers [8] and Lincoln and associates [9]. It also concurs with the series reported by Katz and co-authors [10], which showed that anatomic type is not a determinant of surgical results.

Again, presence of pulmonary venous obstruction preoperatively did not increase surgical mortality in this series. This is in contrast to the reported higher mortality in patients with obstruction in the series by Hammon and associates [7]. Though the 15 patients with obstruction in our series were sicker, once the obstruction was relieved, recovery was fairly quick, and ventilator support beyond 72 hours was very rarely necessary. The important principles of treatment in this series were to intervene early, before substantial depletion and deterioration, and to construct an unrestrictive, wide connection between the veins and the left atrium. These measures enabled prompt resolution of the pulmonary venous obstruction and hypertension. The 72-hour ventilator support has been routine on our service and gave the relatively small and noncompliant left heart chamber time to adapt and maintain full forward cardiac output.

Total anomalous pulmonary venous connection is most often an isolated lesion, and once the operative phase is over, these patients can be expected to do well. Results are uniformly excellent in older patients who are seen late without pulmonary hypertension, but these patients are rare.

The majority of patients in our series were neonates and young infants; 78% had pulmonary hypertension, and 50% had some degree of pulmonary venous obstruction. Still, the late outcome in this group was excellent, and the attrition rate was low. Of the two late deaths, one was due to persistent pulmonary hypertension with no evidence of anastomotic or anatomical obstruction to venous return. This type of inexplicable severe pulmonary hypertension in TAPVC has been well documented [11]. In DeLisle and associates' [11] autopsy series of 93 patients with TAPVC, among patients with markedly elevated pulmonary artery pressure, one fourth had no evidence of obstruction.

The second late death was in a patient who needed two reoperations because of recurrent pulmonary venous obstruction. The stenosis was diffuse and proximal to the anastomosis and resembled a fibrosing mediastinitis with severe fibroplasia. The reoperations during the follow-up in this series involved this patient who did not survive and a second patient with similar obstruction who survived reoperation. This type of diffuse fibrosis, unremitting thickening, and hypertrophy of the endocardium at the pulmonary vein entry sites have been reported by others [3, 4, 8, 12]. The problem in our patient was clearly not anastomotic stenosis as seen by Schäfers and co-

workers [13] in their series. For this reason, we have continued to use very fine nonabsorbable monofilament suture material in the construction of the anastomosis.

The cardiac function in these patients has been uniformly excellent. All but 1 of the surviving patients are totally asymptomatic with no physical restriction. Follow-up echocardiograms of all long-term survivors have shown normal left ventricular wall motion and normal pulmonary venous flow profiles. All patients are in regular sinus rhythm. Similar late functional results have been reported by others [14-16].

These patients have had very acceptable growth and development during long-term follow-up. Height and weight growth percentiles have been less than 5% in only a small portion of the patients. Intellectual development subjectively assessed by pediatricians has been normal in all.

During the past decade, with a consistent surgical approach to neonates and infants with TAPVC, it has been possible to achieve low operative mortality. Early diagnosis and early surgical intervention without attempts at prolonged medical management are important principles of treatment. A wide, unobstructed communication between the left atrium and the common pulmonary venous trunk will provide prompt relief of the pulmonary artery hypertension and pulmonary venous obstruction. Mortality remains high when operations are done within the first 24 hours without a preparatory period to stabilize these sick neonates both metabolically and hemodynamically.

Late survival and functional states have been excellent. Diffuse fibroplasia involving pulmonary vein entry sites remains the major cause of late morbidity and mortality.

DISCUSSION

DR KEVIN TURLEY (San Francisco, CA): I congratulate Dr Cobanoglu on his excellent results in this very difficult group of patients.

Our experience with total anomalous pulmonary venous connection dates back 17 years, and 13 years ago we reported our initial series of 22 patients with this condition operated on between 1975 and 1979. In that series, we advocated a number of changes in approach to these infants. We demonstrated age was not the determinant of survival. In fact, early operation in that series resulted in better results than in many of the previous series where attempts to palliate to prolong the preoperative period and improve the patient's condition resulted in a higher mortality. Since that initial experience, an additional 95 patients have had repair. Of this total of 117 patients, 65 (56%) underwent repair in the first month of life.

In our first series, obstruction was thought to be an important determinant of increased mortality. Fourteen of those 22 patients and all patients with infradiaphragmatic connection had obstruction. In the subsequent 95 patients, we have seen a marked reduction in the number of patients with obstruction at presentation (approximately 50%), with 80% of the patients with infradiaphragmatic type showing obstruction. The mortality rate in the original series was 13%, as in the series of Dr Cobanoglu, and in the subsequent 95 patients, it decreased to 8%. The overall mortality rate for the 117 patients was 9%. In our series as in the series just presented, obstruction is not a determinant of survival.

Finally, in our original 22 patients, the type of lesion was thought to be of importance. Two of our 6 patients with infradiaphragmatic connection died early, and 2 additional patients died late. Those 6 patients represented only 27% of that series,

whereas in the series of Dr Cobanoglu, 57% had infradiaphragmatic connection.

Although the mortality rate has decreased from 13% to 8% in our series, a higher mortality continues to be seen in patients with infradiaphragmatic connection, and it is in this group where the late mortality resulting from diffuse pulmonary venous obstruction occurs. Thus, although type, as Dr Cobanoglu noted, is not a determinant in itself, patients with infradiaphragmatic or mixed-type connection have a higher incidence of small, thick-walled pulmonary veins as opposed to the thin-walled, dilated, proximally obstructed pattern most commonly seen.

In our series, 2 patients with infradiaphragmatic type had persistent pulmonary hypertension. I think this is associated with total anomalous pulmonary venous connection and is a condition we currently cannot treat. However, 6 of the patients had diminutive pulmonary veins. Dr Cobanoglu, did you note the size and configuration of the veins in the patients in your series and in those who have had problems, specifically those with the infradiaphragmatic lesion?

One of your patients is currently symptomatic. Would you describe this patient in more detail as well as the type of lesions in the 4 patients who died early and the 2 who died late?

DR COBANOGU: Thank you very much, Dr Turley. I will echo some of your remarks. We approach these patients very aggressively when they arrive at the neonatal intensive care unit and do not spend days attempting to stabilize their condition metabolically or hemodynamically. We usually try to do whatever we can within a few hours, or within the first 24 hours certainly, and then schedule them for operation. I think some of the improvement is due to this early intervention.

At operation, the surgeon clearly becomes concerned at times after looking at the posterior mediastinum and doing the dissection to delineate the pulmonary venous tract and the veins. I agree with you completely that I feel uneasy about the long-term outcome, not necessarily about the immediate outcome, when I see somewhat thick and small veins entering a large common tract. I know that we can achieve a wide anastomosis in the common tract area, but when the veins entering the collecting vein are thick and somewhat small, this is very bothersome.

As for the patients who died, we did not see a preponderance of a particular anatomic type. In our experience, anatomic type did not correlate with mortality. Among the patients who died, 1 had intracardiac connection, 1 had supracardiac connection, and 2 had infradiaphragmatic connection. Preoperative pulmonary

venous obstruction was seen mostly in patients with infradiaphragmatic connection. As reported in the literature, intracardiac connection in itself is no longer considered a risk factor, and our experience supports this.

DR STEVEN R. GUNDRY (Loma Linda, CA): I congratulate on their very fine results and will briefly present our results, which were recently presented by our fellow, Javier Alonso de Begona, at the Asian cardiothoracic meeting.

My colleagues and I have operated on 33 patients since 1978 and have found much of what the Portland group found. In our series there has been only one death, an infant who was brought to the operating room under full cardiopulmonary resuscitation with ventricular fibrillation. Although he was in stable condition postoperatively, he died of multiorgan failure days later. There have been no late deaths and only one reoperation for pulmonary venous stenosis of a single pulmonary vein. We could find no correlation between survival or late follow-up and type of lesion.

We echo your sentiments that in this day and age, this is no longer a dangerous lesion. We think that the use of circulatory arrest and the variety of surgical approaches have influenced the results. Examples of approach include the transatrial approach, used by my colleague Dr Leonard Bailey, and the superior lifting of the heart approach, which I tend to favor. Both work equally well.

To repeat, I think the expeditious approach to this lesion has totally changed its management.

DR JOSEPH J. AMATO (New Hyde Park, NY): I also congratulate Dr Cobanoglu on his excellent presentation about this complex anomaly. As you had a preponderance of intracardiac type, I wonder whether you ligate and divide the distal pulmonary vein. It was observed in Mr Stark and Dr de Leval's book *Surgery for Congenital Heart Defects* that necrosis of the liver may occur after ligation. I have always divided the distal vein and have never encountered this. Did such necrosis occur in your series, or can you add any knowledge to this topic?

DR COBANOGU: Hepatic necrosis has not been a problem in my experience. The vertical vein, regardless of its direction (infradiaphragmatic or toward the innominate venous system), was closed at the end of the procedure in every patient. We have been very careful about not closing it early during the operation and have used it to vent the left side of the heart during rewarming and resuscitation.

Effects of University of Wisconsin Solution on Endothelium-Dependent Coronary Artery Relaxation in the Rat

Raymond Cartier, MD, Charleen Hollmann, RN, François Dagenais, MD, Josie Buluran, BSc, Michel Pellerin, MD, and Yves Leclerc, MD

Department of Cardiovascular Surgery, Montreal Heart Institute, Montreal, Quebec, Canada

University of Wisconsin (UW) solution has been reported to enhance myocardial preservation in heart transplantation. To evaluate the effects of UW solution on coronary artery endothelial function, we designed experiments to compare UW solution with a standard crystalloid hyperkalemic cardioplegic solution (CHCS). Isolated rat hearts were studied in a modified Langendorff apparatus for coronary endothelial function. Groups 1 and 2 were perfused with 4°C CHCS (24 mmol/L of KCl) and UW solution, respectively, for 10 minutes at a pressure of 80 cm H₂O, whereas group 3 underwent warm ischemia for 10 minutes. Groups 4 and 5 were perfused with and stored for 4 hours in cold (4°C) CHCS and UW solution, respectively. Group 6 underwent 4 hours of topical cooling (4°C) without any cardioplegic perfusion. All groups had 6 hearts each. Endothelium-dependent relaxation and endothelium-independent relaxation of the coronary arteries were tested by infusing 5-hydroxytryptamine (5HT) (10^{-6} mol/L) and sodium nitroprusside (10^{-5} mol/L), respectively, before and after perfusion with and storage

in one of the two cardioplegic solutions. The coronary vasodilatation induced by 5HT and sodium nitroprusside was not altered in hearts perfused with (group 1) or perfused with and stored in CHCS (group 4). Coronary flow increase after 5HT infusion was significantly decreased in hearts perfused with (group 2) (before, $35\% \pm 10\%$; after, $13\% \pm 10\%$; $p < 0.01$) or perfused with and stored in UW solution (group 5) (before, $34\% \pm 5\%$; after, $-5\% \pm 12\%$), indicating severe endothelial dysfunction. In the latter group, coronary flow increase with sodium nitroprusside was also decreased, a finding suggesting smooth muscle damage (before, $84\% \pm 35\%$; after, $30\% \pm 15\%$). Coronary arteries of hearts having 4 hours of cold ischemia alone (group 6) had a significant decrease only in flow response to 5HT stimulation (before, $60\% \pm 23\%$; after, $24\% \pm 12\%$). These experiments suggest that perfusion with and storage in UW solution does not preserve endothelium-dependent coronary relaxation in the isolated rat heart.

(*Ann Thorac Surg* 1993;55:50-6)

Optimal myocardial preservation remains a major concern in heart transplantation. Acceptable myocardial protection can be obtained for 4 to 6 hours with a cardioplegic or normal saline rinse followed by cold crystalloid preservation [1, 2]. Encouraging results have been obtained both experimentally and clinically in heart transplantation with the use of University of Wisconsin (UW) solution. However, the usefulness of this solution in enhancing long-term heart preservation is still controversial [3-8]. First designed for preservation of the pancreas, and then kidney and liver preservation, its application to heart transplantation has raised hope for a longer period of optimal preservation. Despite the fact that UW solution could contribute to the improvement of myocardial preservation during storage, the effect on coronary artery endothelial reactivity has not been determined.

The vascular endothelium plays a major role in arterial vasoregulation. Besides producing antithrombotic substances such as prostacyclin, antithrombin III, plasmin

activator, protein C, and α_2 -macroglobulin, endothelial cells release nonprostanoid vasoactive compounds called endothelium-derived relaxing factors (EDRFs), nitric oxide being one of these [9-12]. Release of nitric oxide has major effects on local vasoregulation, not only because nitric oxide is a powerful muscle relaxant, but also because it is an inhibitor of platelet adhesion and aggregation. Loss of endothelial responsiveness during myocardial storage will increase the thrombogenicity of the vascular wall to the aggregating platelets and could compromise the blood supply of the donor heart. It also has been reported that vessels with chronically regenerated endothelium do not resume normal vasoregulatory function but rather have an increased risk of vasospasm [13-16]. Then it is imperative to preserve the vascular endothelial function of the donor heart to assume optimal graft survival.

Previous reports indicate that infusion of crystalloid hyperkalemic cardioplegic solution (CHCS) could impair 5-hydroxytryptamine (5HT)-induced endothelium-dependent coronary relaxation in the isolated Langendorff-perfused rat heart, although others have claimed that this impairment might be related to mechanical and time

Presented at the Twenty-eighth Annual Meeting of The Society of Thoracic Surgeons, Orlando, FL, Feb 3-5, 1992.

factors rather than CHCS infusion itself [17-19]. No data, however, are available on the effect of UW solution perfusion and storage on the coronary vasoregulation of the rat heart.

This study was designed to evaluate the effect of UW solution on endothelium-dependent coronary artery relaxation in the isolated rat heart model after perfusion with and cold storage in UW solution.

Material and Methods

Animal Preparation and Reagents

Hearts were obtained from male Sprague-Dawley rats weighing 250 to 300 g and maintained on a standard laboratory diet. 5-Hydroxytryptamine and sodium nitroprusside (SNP) were obtained from Sigma Chemicals Ltd, St. Louis. Crystalloid cardioplegia was obtained from the Montreal Heart Institute pharmacy and UW solution, from Dupont Pharma, Toronto (Table 1). All animals were cared for in compliance with the "Guide for the Care and Use of Laboratory Animals" published by the National Institutes of Health (NIH publication No. 85-23, revised 1985).

Perfusion Technique

The rats were heparinized (3 mg/kg) and decapitated. The chest was immediately opened, and the aorta was isolated, cannulated, and perfused in vivo with 37°C oxygenated (95% O₂ and 5% CO₂) Krebs-Ringer solution ([mmol/L]: NaCl, 118.3; KCl, 4.7; MgSO₄, 1.2; KH₂PO₄, 1.22; CaCl₂, 1.3; NaHCO₃, 25.0; and glucose, 15; pH 7.4 at 37°C). The perfused hearts were excised from the chest

and mounted onto a modified Langendorff apparatus [20]. Using this harvesting technique, myocardial ischemia was kept to less than 45 seconds. The perfusion pressure was maintained at 80 cm H₂O. The hearts were atrially paced at 300 to 350 beats per minute. The maximum left ventricular pressure and rate of change of LVP (dP/dt) were measured by inserting a latex balloon inside the left ventricle through the left atrium and inflating it to maintain a left ventricular end-diastolic pressure of 10 mm Hg. Left ventricular pressure was measured with a Gould transducer signal conditioner (Gould 20-4615-50), and dP/dt was recorded using a Gould differentiator signal conditioner (Gould 13-G4615-71). The mean and pulsatile coronary flows were measured using a 2-mm factory-precalibrated cannulating ultrasonic probe (Transonic cannulating flow probe type 2N; internal diameter, 3.2 mm; resolution, 0.1 mL/min; Transonic Systems Inc) to which the aorta was attached. Two hearts were studied simultaneously in two Langendorff apparatuses and all data recorded on an eight-channel Gould recorder.

Drugs were dissolved in Krebs-Ringer solution and perfused with a Harvard syringe infusion pump 22 (Harvard Apparatus) to assure a constant drug delivery (5HT, 10⁻⁶ mol/L; SNP, 10⁻⁵ mol/L) during coronary perfusion.

Protocol

After harvesting, hearts were perfused and stabilized for a period of 30 minutes in the Langendorff apparatus. At the end of this period, coronary flow, dP/dt, and LVP were recorded for baseline values. Then 5HT and SNP were sequentially infused into the rat aorta through the cannula for 4 minutes each. Changes in coronary flow were recorded at the end of the 4-minute infusion. Each drug infusion was followed by a 30-minute washout period to allow the coronary flow to return to control values. The drugs were always administered in the same sequence, 5HT first followed by SNP 30 minutes later...

After these steps, hearts were exposed to perfusion with and storage in different cardioplegic solutions as described in the Experimental Design section. This was followed by a 30-minute recovery period, during which hearts were reperfused with 37°C Krebs-Ringer solution at a perfusion pressure of 80 cm H₂O. Coronary flow, dP/dt, and LVP were recorded at the end of the recovery period. Hearts then underwent 5HT and SNP infusion again and changes in coronary flow were recorded as previously described.

Experimental Design

PART I. The first set of experiments was designed to assess coronary endothelial function after a short perfusion with UW solution or CHCS. In group 1 (n = 6), hearts were perfused with 4°C CHCS at 80 cm H₂O pressure for 10 minutes. In group 2 (n = 6), hearts were perfused with UW solution at the same pressure and for the same time. In group 3 (n = 6), hearts were exposed to 10 minutes of warm ischemia by cross-clamping the cannula just above the perfused aorta. This group served as the controls to measure the effect of warm ischemia alone.

PART II. The second set of experiments was specifically designed to assess endothelium-dependent coronary artery relaxation after long-term preservation. Hearts in group 4 ($n = 6$) were first perfused with 4°C CHCS (perfusion pressure, 80 cm H₂O; perfusion time, 10 minutes) to induce myocardial arrest and then preserved for 4 hours in the same solution (4°C). Hearts in group 5 ($n = 6$) were similarly arrested with UW solution perfusion and stored in the same solution for 4 hours. Hearts in group 6 ($n = 6$) were stored in an isotonic solution (0.09% NaCl) for 4 hours at 4°C. In this group, unlike groups 4 and 5, the solution was not allowed to get in physical contact with the coronary endothelium (the aortic cannula was kept cross-clamped). This was done specifically to evaluate the effect of topical cooling alone.

Data Analysis

Baseline flow is recorded in milliliters per minute. Changes in coronary artery flow before and after exposure to perfusion with and storage in the different solutions are reported as percent change versus the baseline value. All data are expressed as the mean $\pm$ the standard deviation. Statistical analysis was performed with Student's paired t test. The significance of differences was established at 95% ($p < 0.05$).

Results

Part I (Perfusion Alone)

ENDOTHELIAL AND SMOOTH MUSCLE RESPONSIVENESS. Group 1 hearts perfused with CHCS reacted similarly to 5HT and SNP infusion both before and after perfusion, indicating that muscle tone and endothelial reactivity were still present and not affected by the perfusion (Fig 1).

The group 2 hearts were perfused with UW solution. The perfusion significantly reduced the 5HT-induced coronary relaxation ($35\% \pm 10\%$ versus $13\% \pm 10\%$), indicating severe endothelial dysfunction (see Fig 1A). Coronary vasodilatation after SNP infusion was also diminished, indicating some decrease in smooth muscle responsiveness ($79\% \pm 19\%$ versus $62\% \pm 6\%$; $p = 0.06$) (see Fig 1B).

Group 3 was not exposed to any specific preservation solution but did have a warm ischemic period of 10 minutes. The coronary responsiveness to 5HT infusion was decreased to a certain extent ($35\% \pm 8\%$ versus $24\% \pm 7\%$; $p =$ not significant), whereas coronary flow response to SNP remained unaffected ($67\% \pm 22\%$ versus $66\% \pm 22\%$) (see Fig 1).

CORONARY FLOW. Coronary flow was significantly reduced in group 1 after CHCS perfusion (Table 2). It remained unaffected in groups 2 and 3.

GLOBAL HEART FUNCTION. Left ventricular systolic pressure and dP/dt remained unchanged throughout this part of the study (Table 3).

Part II (Perfusion and Storage)

ENDOTHELIAL AND SMOOTH MUSCLE RESPONSIVENESS. In group 4, hearts were arrested with 10-minute perfusion

Fig 1. Percent increase in coronary flow induced by (A) 5-hydroxytryptamine (10^{-6} mmol/L) and (B) sodium nitroprusside (10^{-5} mmol/L) before (open bars) and after (solid bars) 10-minute perfusion with 4°C crystalloid hyperkalemic cardioplegic solution (CHCS) or University of Wisconsin solution (UW) or after 10 minutes of warm ischemia (ISCH).

and stored in CHCS. Vascular endothelial and smooth muscle functions were not significantly affected after storage (Fig 2).

Group 5 hearts perfused with and stored in UW solution showed severe impairment of 5HT-induced coronary artery vasodilatation ($34\% \pm 5\%$ versus $-5\% \pm 12\%$; $p < 0.01$) and a significant decrease in smooth muscle response to SNP ($84\% \pm 35\%$ versus $30\% \pm 15\%$; $p < 0.05$) (see Fig 2).

Table 2. Baseline Coronary Artery Flow at the Beginning of the Experiment and After the Recovery Period

Group	Baseline Flow (mL/min)		p Value
	Before	After	
1	6.7 $\pm$ 0.8	5.4 $\pm$ 1.0	<0.05
2	10.0 $\pm$ 1.5	10.0 $\pm$ 2.1	NS
3	6.8 $\pm$ 0.3	6.2 $\pm$ 0.5	NS
4	7.6 $\pm$ 1.4	5.3 $\pm$ 0.7	<0.01
5	6.3 $\pm$ 1.0	6.3 $\pm$ 2.9	NS
6	6.9 $\pm$ 0.6	6.3 $\pm$ 1.4	<0.01

NS = not significant.

Table 3. Rate of Rise of Left Ventricular Pressure and Left Ventricular Pressure at the Beginning of Experiment and After Recovery Period

Group	dP/dt (mm Hg/s)		LVP (mm Hg)	
	Before	After	Before	After
1	1,450 ± 150	1,425 ± 458	65 ± 5	56 ± 11
2	1,240 ± 600	1,160 ± 600	62 ± 19	46 ± 15
3	1,880 ± 450	1,900 ± 500	77 ± 20	81 ± 24
4	1,900 ± 580	1,500 ± 390	70 ± 17	57 ± 10
5	1,500 ± 370	775 ± 735 ^a	67 ± 10	35 ± 20 ^b
6	1,120 ± 500	1,080 ± 600	63 ± 12	59 ± 13

^aSignificance: $p = 0.06$.

^bSignificance: $p < 0.05$.

dP/dt = rate of change of left ventricular pressure; LVP = left ventricular pressure.

Group 6 hearts had 4 hours of cold ischemia without cardioplegic arrest and displayed a significant decrease in 5HT-induced coronary artery response ($60\% \pm 23\%$ versus $24\% \pm 12\%$; $p < 0.01$). Smooth muscle response was not affected ($72\% \pm 18\%$ versus $80\% \pm 35\%$) (see Fig 2).

CORONARY FLOW. Coronary flow was significantly affected in groups 4 and 6 (see Table 2). Only hearts perfused and stored in UW solution were not affected.

GLOBAL HEART FUNCTION. There was a decrease in LVP (70 ± 9 mm Hg versus 35 ± 19 mm Hg; $p < 0.05$) and dP/dt ($1,525 \pm 370$ mm Hg/s versus 775 ± 700 mm Hg/s; $p = 0.06$) in hearts preserved with UW solution (see Table 3). Topical cooling alone and storage in 4°C CHCS did not alter global heart function.

Comment

These experiments demonstrate that perfusion with and storage in different preservation solutions could be detrimental to the endothelium-dependent coronary artery relaxation of the isolated rat heart. A normal endothelial capacity to release EDRFs is essential to assure optimal graft preservation during heart transplantation by protecting coronary vessels against vasospasm and thrombi formation during reperfusion [21, 22]. There is also experimental evidence that once the endothelium is made dysfunctional (subsequent to ischemic or mechanical injury), it does not resume normal function; rather, such injury leads to chronically increased vascular tone [13, 14, 16] and can also contribute to early atherosclerosis [23].

5-Hydroxytryptamine was chosen to evaluate coronary endothelial function in this model because 5HT has been shown to stimulate coronary artery relaxation through nitric oxide release in the rat [24]. In these conditions, 5HT activates endothelium-dependent serotonergic receptors and releases nitric oxide, which relaxes the smooth muscle by increasing cyclic guanosine monophosphate [25]. Sodium nitroprusside relaxes smooth muscle by increasing the content of cyclic guanosine monophosphate in vascular smooth muscle through an endotheli-

um-independent pathway, and its action can be preserved even when the endothelium is dysfunctional [25].

In this study, we have shown that perfusion with or without subsequent storage in a pH-balanced CHCS containing 24 mmol of KCl per liter creates minimal endothelial and smooth muscle damage when the infusion pressure is kept at 80 cm H₂O and infusion time is limited to 10 minutes. A short perfusion with UW solution was found to cause more damage to coronary artery endothelial responsiveness than ischemia alone. The combination of perfusion and 4-hour storage was even more detrimental to endothelial function. Baseline coronary flow was affected in hearts perfused with and stored in CHCS and also in those stored for 4 hours without preservation solution after cold ischemia alone. Perfusion with and storage in UW solution did not affect baseline coronary flow.

Global heart function as evaluated by LVP and dP/dt was affected only in hearts perfused with and preserved in UW solution. This finding indicates that the ischemic periods (10 minutes and 4 hours) used in these experiments were not responsible for altering global heart function.

Fig 2. Percent increase in coronary flow induced by (A) 5-hydroxytryptamine (10^{-6} mmol/L) and (B) sodium nitroprusside (10^{-5} mmol/L) before (open bars) and after (solid bars) 10-minute perfusion with and 4-hour cold (4°C) storage in crystalloid hyperkalemic cardioplegic solution (CHCS) or University of Wisconsin (UW) solution or 4 hours of topical cooling alone (CONTROL).

The formulation of UW solution was designed to address several theoretical and practical concerns. Various components are added to decrease cellular acidosis and swelling, prevent free radical-mediated reperfusion injury, stabilize membranes, and facilitate adenosine triphosphate regeneration [6]. The solution contains a high K^+ and low Na^+ concentration, and two nonmetabolized, osmotically active large molecular agents, potassium lactobionate and the saccharide raffinose [26, 27]. These prevent cellular swelling caused by anaerobic, hypothermic-induced Na-K ATPase suppression and prevent sodium and chloride from entering the cell [28]. All these components may affect the endothelium.

Potassium in CHCS has been blamed for causing endothelial functional alteration [16, 17]. Nevertheless, we [19] have established that a high KCl concentration (100 mmol/L) could be used in conjunction with CHCS provided perfusion pressure was kept to 80 cm H_2O and infusion time to 10 minutes. The potassium concentration is probably not the only factor responsible for endothelial damage. The osmotically active, large-molecule agents and the hydroxyethyl starch (Pentastarch) used in the UW solution increase its viscosity compared with standard cardioplegia. This higher viscosity (observed after we found the Langendorff apparatus extremely hard to clean after the experiment) combined with the hydrostatic pressure of the perfusion increases intravascular shear stress and can potentially damage the endothelium.

In certain experimental conditions, storage in UW solution has been shown to preserve nitric oxide production, cell morphology, adenosine triphosphate levels, and viability of artificially grown endothelial cells [29, 30]. The experimental designs of these studies depart substantially from the design used in our model. In these studies, endothelial cells were not subjected to any specific hemodynamic variables such as infusion velocity or hydrostatic pressure. In the isolated rat heart model, changes in coronary flow result from variation in resistance arterioles, which are small-diameter vessels. Energy losses associated with fluid flow are mainly related to the viscosity of the fluid and its inertia. Because energy losses are inversely proportional to the fourth power of the radius, the endothelial cells of coronary arterioles are more susceptible to damage by high shear stress when the viscosity of the solution is increased [31].

In Figure 3, a sample of the coronary flow changes observed during CHCS and UW solution perfusion is displayed. The top part of the figure represents flow changes during CHCS perfusion. Flow acutely increases as perfusion starts and slowly returns to the preinfusion level. This flow increase, even though the perfusion pressure was kept constant, can be caused by the lower temperature of the cardioplegic solution. Lowering the temperature has been shown to augment the sensitivity of vascular smooth muscle to EDRFs in the rat [32]. Contrary to that, during cold UW perfusion (bottom part), coronary flow decreases sharply at the very beginning, rapidly increases to half the level of the preinfusion flow, and returns to normal only when perfusion is completed. This suggests an acute increase in vascular resistance possibly

Fig 3. Baseline flow pattern during perfusion with crystalloid hyperkalemic cardioplegic solution (CHCS) or University of Wisconsin solution (UW). Broken line represents the period of solution perfusion. See Comment section for explanation.

caused by high KCl content or flow obstruction related to fluid viscosity.

The amount of solution given during the 10-minute perfusion period was significantly higher in the CHCS group, which confirms the lower vascular resistance in this group (80 ± 15 mL versus 41 ± 7 mL; $p < 0.01$). This could explain part of the endothelial injury related to the UW solution. Interestingly, baseline flow was not affected in the UW solution-preserved hearts. The reason for this is unclear. Coronary flows in hearts perfused with and stored in CHCS or just stored without any preservation solution were consistently decreased after storage, a finding suggesting a reduction in baseline EDRF release even though the EDRF release to a 5HT bolus was preserved. Despite the fact that coronary flow was significantly lowered during UW perfusion, this effect was not sustained.

In regard to global heart function, our results differ from those obtained in other experimental and human studies. Part of the explanation may come from oxidized glutathione, present in aged shelf-stored UW solution. Oxidized glutathione has been associated with decreased efficiency in heart preservation [33]. Reduced glutathione is added to chemically reduce cytotoxic oxidants and suppress lipid peroxidation [6]. With time, it converts to its oxidized form, which is an efficient activator of the collagenolytic system, both in vitro and in vivo, causing structural damage during long-term preservation [34-36]. The UW solution used in this study was not freshly prepared but shelf stored, following the manufacturer's recommendations and used with respect to the expiration date. The amount of oxidized glutathione was not measured. Moreover, the acalcemic composition of the UW solution has also been found to cause calcium paradox-related myocyte injury during reperfusion [8]. As the Krebs solution used in our experiment contains calcium, it may have contributed to reperfusion injury. All these factors may explain the nonoptimal vascular smooth muscle and myocyte preservation observed in this study.

In conclusion, this study highlights interesting points regarding endothelial vascular function in myocardial protection. Extracellular-formulated solutions with buffer capability and osmotically active agents seem to offer good functional preservation of myocyte and coronary artery endothelial reactivity. In regard to UW solution employed either as a cardioplegic or preservation solution, further investigation is needed before its use in human heart transplantation can be recommended, as endothelium-dependent coronary relaxation was poorly preserved. Efforts to improve myocardial protection should consider endothelial preservation as much as myocyte preservation.

DISCUSSION

DR IRVING L. KRON (Charlottesville, VA): I agree entirely with your conclusions in the animal model. At the recent American Heart Association meeting, my colleagues and I presented some work using an isolated vascular ring model in rabbits and found the exact same effect. How do you explain the paradox that some clinical investigators have noted excellent preservation with UW solution?

DR CARTIER: This is a good question. Investigators who reported good results used a cultured cell model in which endothelial cells are grown on microcarrier beads and then exposed to UW solution. In that model without a vascular network, the endothelial cells are not subjected to the same hydrostatic pressure and shear stress conditions. The results cannot be compared. Furthermore, we did not use freshly made UW solution but the commercially available one currently used for liver transplantation. The reduced glutathione contained in the shelf-stored solution could be responsible for the poor preservation seen in our model.

DR AXEL HAVERICH (Hannover, Germany): I very much enjoyed this presentation because it highlights some problems about the high potassium concentration in the UW solution. My associates and I were very concerned about the potassium concentration before we performed our prospective, randomized clinical trial comparing UW solution and St. Thomas' Hospital solution for cardioplegia in patients undergoing heart transplantation.

Because of our concerns, we measured coronary flow and coronary vascular resistance at 5 and 10 minutes' reperfusion of the transplanted hearts after a mean ischemic time of 150 minutes. Surprisingly, we did not find the same results that you presented in your experimental study. There was no difference in coronary flow or coronary vascular resistance between UW-preserved hearts and hearts preserved with St. Thomas' Hospital solution. Also, there was much better recovery of electrical function in the donor hearts, and at 1 day, 2 days, and 4 days after transplantation, left ventricular function and right ventricular function were comparable in the two groups. There was no difference in regard to these indices when comparing UW solution and St. Thomas' Hospital solution.

DR CARTIER: This is an interesting point. I did not comment about baseline coronary flow in the presentation. When we measured baseline coronary flow before and after perfusion with UW solution or regular cardioplegic solution, we did not find any significant difference between solutions. Changes were observed only when we looked for endothelium-derived relaxing factor production by the coronary endothelium. In our model, the endothelium-dependent coronary vasorelaxation was severely

impaired in hearts perfused with or perfused with and stored in UW solution. Simply looking at baseline coronary flow does not allow any conclusion about vascular endothelial preservation.

DR JAMES C. STRINGHAM (Madison, WI): I am very interested in your results, particularly in light of the data I presented previously, because my associates and I also found a loss of coronary flow, even when hearts functioned very well. I think your point about shear stress is a good one, especially in small hearts like that of the rabbit or the rat. In our study, we found that rabbit hearts perfused at a pressure of 80 or 100 cm H₂O did not function well, and we actually had to lower perfusion pressure to 50 cm H₂O to get them to function better. So I think that may be an important point and may explain why some of the microvasculature seems to be damaged.

I also think your point about potassium is a good one. This continues to be a challenge and a controversy when using UW solution in the heart, and the potassium concentration may have to be lowered. Did you ever try using a UW solution with an altered potassium concentration, or did you try using a decreased coronary perfusion pressure in your model?

DR CARTIER: These are interesting comments. We have not tried using UW solution with a lower potassium concentration. However, we have shown in a previous study that potassium used in conjunction with regular cardioplegic solution could be infused at a very high concentration (100 mmol/L) without endothelial damage provided perfusion pressure and duration of perfusion were limited. We found that these conditions were a perfusion pressure of 80 cm H₂O and a perfusion period of 10 minutes. Increasing the perfusion pressure to 160 cm H₂O completely destroyed the endothelial responsiveness. Then potassium concentration is probably an important factor, although maybe not as much as viscosity and shear stress at the microvascular level. Trying the same experiments at a lower perfusion pressure is an excellent suggestion.

DR ADNAN COBANOGLU (Portland, OR): Dr Cartier, how about the osmolality of the UW solution? There are some data from the Hershey group that as osmolality is reduced, preservation, both functional and biochemical, is better.

DR CARTIER: That is a good point. The osmolality of the UW solution is 320 mosm/L, which is not very high. If you want to reduce it, you have to remove components of the solution, and the question is, which ones are we going to remove? We did studies using a solution with an osmolality approaching 500 mosm/L, and again, endothelial damage was related to high (160 cm H₂O) perfusion pressure. However, we did not study long-term preservation with these solutions.

Cerebral Metabolism and Circulatory Arrest: Effects of Duration and Strategies for Protection

James R. Mault, MD, Shigeaki Ohtake, MD, Mary E. Klingensmith, BA,
Jeffrey S. Heinle, MD, William J. Greeley, MD, and Ross M. Ungerleider, MD

Departments of Surgery and Anesthesiology, Duke University Medical Center, Durham, North Carolina

Hypothermic total circulatory arrest (CA) is commonly used to facilitate repair of complex congenital heart defects. However, the "safe" period of CA remains to be defined. Extended periods of hypothermic total circulatory arrest may impair cerebral metabolism and cause ischemic brain injury. This study defines the relationship between increasing durations of CA at 18°C and cerebral metabolism, and examines the protective value of topical cooling of the head or continuous "trickle" flow (5 to 10 mL · kg⁻¹ · min⁻¹). Thirty-three 1-week-old piglets were randomized to six experimental groups: control; 15, 30, or 60 minutes of CA; 60 minutes of CA with topical cooling of the head; and 60 minutes of trickle flow. Animals were placed on cardiopulmonary bypass (CPB) at 100 mL · kg⁻¹ · min⁻¹ and cooled to 18°C. After the experimental period of CA or trickle flow (or 60 minutes of CPB at normal flow for the control

group), animals were rewarmed to 37°C and weaned from CPB. Data were obtained before and immediately after CPB at 37°C, and before and immediately after the experimental period at 18°C. Parameters measured included cerebral blood flow by xenon 133 clearance, arterial and sagittal sinus blood gases, and cerebral metabolism. Hypothermic total circulatory arrest caused an impairment of cerebral metabolism that was directly proportional to CA duration ($r^2 = 0.73$; $p = 0.0001$), and recovery of metabolic function after 60 minutes of CA improved more than 50% if the head was packed in ice. If technically feasible, CPB flow of only 5 to 10 mL · kg⁻¹ · min⁻¹ during hypothermia is superior to CA with respect to cerebral protection. Future studies with this model can be used to develop optimal modes of cerebral protection during neonatal heart operations.

(*Ann Thorac Surg* 1993;55:57-64)

Deep hypothermic circulatory arrest (CA) is an intraoperative technique commonly used during repair of congenital heart lesions. The theoretical basis for the use of total CA for cardiac operations is that a "safe" duration exists, the length of which is inversely proportional to the temperature of the organism during the arrest period [1]. In clinical practice, a short period of hypothermic CA is considered to be well-tolerated. Conversely, durations of CA extending beyond some safe limit are thought to cause cerebral ischemia and brain injury. However, these time points are poorly defined, and it is more likely that a spectrum of effects occurs between the two extremes. Better characterization of the pattern of response to CA will facilitate objective evaluation of current techniques and the development of new methods of cerebral protection.

This study was conducted with two objectives: (1) to define the pattern of cerebral response to increasing durations of hypothermic CA and (2) to evaluate two commonly employed strategies (topical cooling of the head and "trickle flow" bypass) that may alter this response and thereby provide a longer period of safety for operative repairs. The protocol and techniques used in

this investigation were designed to duplicate those used in the routine clinical setting.

Material and Methods

Animal Preparation

All animal experiments were conducted with the approval of the institution's Animal Care and Use Committee and received humane care in compliance with the "Guide for the Care and Use of Laboratory Animals" published by the National Institutes of Health (NIH publication No. 85-23, revised 1985). Thirty-three 1-week-old piglets (2 to 3 kg) were preanesthetized with ketamine (20 mg/kg), intubated, and mechanically ventilated (Infant Ventilator; Sechrist Industries, Anaheim, CA). Animals were paralyzed with pancuronium (0.1 mg/kg), and anesthesia was maintained by a continuous fentanyl infusion (50 µg · kg⁻¹ · h⁻¹). Nasopharyngeal and rectal temperature probes were placed and a femoral artery catheter was inserted for continuous blood pressure monitoring and arterial blood gas sampling. Animals then underwent median sternotomy. Cardiac instrumentation consisted of a left atrial catheter for xenon 133 injection, a pulmonary artery catheter for mixed-venous blood gas sampling, and an 8-mm flow probe (Transonic Systems, Ithaca, NY) positioned around the pulmonary artery for measurement of cardiac output.

Measurement of Cerebral Blood Flow

Cerebral blood flow (CBF) was determined by the xenon (^{133}Xe) clearance technique. Two brass-insulated cadmium telluride gamma emission detectors (approximately 1 cm in diameter) were positioned extracranially over the right and left temporal lobes. Xenon (1.5 mCi in 2 mL of normal saline solution) was injected into the arterial circulation through the left atrial catheter (or through the aortic cannula during cardiopulmonary bypass [CPB]). Radioactive decay was recorded separately from each hemisphere over 15 minutes. Cerebral blood flow was then derived from the radioactive decay curves using a modification of the initial slope index method [2] as follows: $\text{CBF} = (\text{slope})(\lambda)(100)$, where slope is the natural logarithm of the ^{133}Xe clearance curve 1 minute after the injection peak, λ is the tissue-blood partition coefficient for xenon, corrected for hematocrit and temperature [3], and 100 is for conversion of units from $\text{mL} \cdot \text{g}^{-1} \cdot \text{min}^{-1}$ to $\text{mL} \cdot 100 \text{ g}^{-1} \cdot \text{min}^{-1}$. Cerebral blood flow was determined for each cerebral hemisphere and averaged to derive the global CBF.

Measurement of Cerebral Metabolism

At each stage of the experiment, sagittal sinus blood was sampled through the midline sagittal suture. The cerebral arteriovenous oxygen content difference (cer Ca-vO_2) was then calculated as $\text{CaO}_2 - \text{CvSO}_2$, where CaO_2 is arterial oxygen content and CvSO_2 is the sagittal sinus oxygen content. Blood gases were measured by a GEM-STAT Blood Gas/Electrolyte Monitor (Mallinckrodt, Ann Arbor, MI). After measurement of CBF by xenon clearance, cerebral metabolism (CMRO_2), cerebral oxygen delivery (cer DO_2), and cerebral oxygen extraction ratio (cer O_2 Ext Ratio) were calculated as follows:

$$\text{CMRO}_2 (\text{mL O}_2 \cdot 100 \text{ g brain}^{-1} \cdot \text{min}^{-1})$$

$$= (\text{cer Ca-vO}_2)(\text{CBF})$$

$$\text{cer DO}_2 (\text{mL O}_2 \cdot 100 \text{ g brain}^{-1} \cdot \text{min}^{-1})$$

$$= (\text{CaO}_2)(\text{CBF});$$

$$\text{cer O}_2 \text{ Ext Ratio} = \text{CMRO}_2 / \text{cer DO}_2.$$

Cardiopulmonary Bypass Technique

The CPB circuit consisted of a Stöckert-Shiley (Irvine, CA) CAPS nonpulsatile roller pump and a Cobe VP-CML (Denver, CO) membrane lung with venous reservoir. A CDI-300 (CDI; 3M Healthcare, Irvine, CA) continuous in-line blood gas analyzer was used on the arterial and venous limbs to precisely control circuit blood gases. The circuit prime consisted of fresh donor pig whole blood with a hematocrit ranging from 0.22 to 0.26. After heparinization (1,000 U/kg), 8F arterial and 14F venous cannulas were placed in the aortic root and right atrium, respectively. Cardiopulmonary bypass before and after the experimental period was maintained at $100 \text{ mL} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$ to duplicate the normal cardiac output of the piglet. Blood pressure was allowed to vary without intervention. Circuit blood gases were managed according to the alpha-stat protocol

[4] and maintained pH at 7.35 to 7.40 and carbon dioxide tension at 35 to 40 mm Hg, uncorrected for temperature.

Experimental Protocol and Data Collection Sequence

Data collection was divided into four stages (Fig 1). Data first were collected at 37°C immediately before cannulation for CPB (Pre). After cannulation and initiation of CPB at $100 \text{ mL} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$ and 37°C , animals were cooled by perfusion over 30 minutes to 18°C pharyngeal temperature and the first hypothermia data were collected (HT1). Animals were then randomized to one of six experimental groups as described in Figure 1. Animals in the control group were cooled to 18°C and maintained on CPB at $100 \text{ mL} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$ for 60 minutes without any period of CA. Three groups of animals underwent CA at 18°C for durations of either 15, 30, or 60 minutes. Two cerebral protection strategies were also tested: 60 minutes of CA with the head packed in ice during the CA period, and continuous CPB at 5 to $10 \text{ mL} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$ at 18°C for 60 minutes. Upon completion of the respective experimental period, CPB was reinstituted at $100 \text{ mL} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$ and 18°C and data were collected after stabilization for 10 minutes (HT2). Animals were then rewarmed to a pharyngeal temperature of 37°C and weaned from CPB. Measurements were taken immediately after hemodynamic and ventilatory stability was achieved (approximately 30 minutes after CPB) (Post). Data collection at each of these stages consisted of pharyngeal and rectal temperatures; heart rate; blood pressure; cardiac output; pump flow; arterial, sagittal sinus, and pulmonary artery blood gases; hematocrit; electrolytes; ionized calcium; and CBF. In addition to cerebral oxygen delivery and metabolism, total systemic oxygen consumption and systemic oxygen extraction ratio were calculated by the Fick equation using cardiac output with arterial and mixed-venous blood gases.

Statistical Analysis

Data were collated and statistically analyzed using the paired *t* test to compare Pre versus Post CPB and HT1 versus HT2 results for each experimental group. Post CPB results were compared between groups using analysis of variance. Statistical significance was tested at the 95% confidence level. All results are expressed as the mean value $\pm$ the standard error of the mean.

Results

All animals completed each stage of the study successfully. Total study time from induction of anesthesia to Post data collection was 4 ± 0.5 hours depending on experimental group.

General Effects of Hypothermia

Pre and HT1 values for all animals are listed in Table 1. As compared with Pre values at normothermia, perfusion cooling to 18°C caused significant reductions in heart rate, CMRO_2 , cerebral oxygen extraction ratio, and systemic oxygen consumption. However, despite cooling over 30 minutes, CMRO_2 was reduced by only $56.5\% \pm 3.7\%$ in

Fig 1. Experimental protocol and data collection sequence: After anesthesia and instrumentation was accomplished, baseline (Pre) measurements were obtained. Animals were then cannulated and placed on cardiopulmonary bypass (CPB) at $100 \text{ mL} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$ and 37°C , then perfusion-cooled to 18°C over 30 minutes. Data were obtained on full CPB immediately before the experimental period (HT1) and after the experimental period (HT2) on full CPB. The groups studied during the experimental period were as follows: (1) Control 18°C CPB at $100 \text{ mL} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$ for 60 min ($n = 5$); (2) 15 minutes of total circulatory arrest at 18°C (15°CA ; $n = 5$); (3) 30 minutes of total circulatory arrest at 18°C (30°CA ; $n = 6$); (4) 60 minutes of total circulatory arrest at 18°C (60°CA ; $n = 6$); (5) 60 minutes of total circulatory arrest with cerebral topical cooling (60°CA-TC ; $n = 6$); and (6) 60 minutes of trickle-flow CPB at 5 to $10 \text{ mL} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$ (60°TF ; $n = 5$). Animals were then rewarmed to 37°C and weaned off CPB. Final measurements were obtained after stabilization for 30 minutes (Post).

all animals. In the experimental groups that were subjected to CA, the CMRO_2 immediately before initiation of CA averaged $41.8\% \pm 4.2\%$ of baseline oxygen requirements. Systemic and cerebral arteriovenous oxygen content differences decreased with cooling, whereas mean arterial pressure, systemic perfusion, cerebral blood flow, and cerebral oxygen delivery were not statistically different.

Effects of Circulatory Arrest and Protective Measures on Cerebral Metabolism During Hypothermic Perfusion

Upon completion of the experimental period (HT2) and reinstitution of CPB at $100 \text{ mL} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$ and 18°C , the effects of CA and cerebral protective methods were recorded and are listed in Table 2. Compared with HT1 values, CMRO_2 at HT2 was significantly impaired in groups receiving 15, 30, or 60 minutes of CA, whereas pharyngeal temperatures and CBF were unchanged. Top-

ical cooling of the head during 60 minutes of CA significantly reduced pharyngeal temperature to an average of $12.6^\circ \pm 1.4^\circ\text{C}$, and CMRO_2 was fully recovered. Trickle flow for 60 minutes also sustained CMRO_2 , which was significantly greater when compared with values in the CA groups at HT2.

Effects of Circulatory Arrest on Cerebral Metabolism After Weaning From Cardiopulmonary Bypass

Pre and Post CPB values for several indices of cerebral metabolism are listed in Table 3. In control animals, all indices returned to baseline values, and hypothermic CPB demonstrated no measurable effect on CMRO_2 after re-warming. In the groups subjected to a period of CA, CMRO_2 was significantly impaired when compared with Pre values within each group, as well as when compared with the control Post values between groups. When expressed as a percent recovery of Pre values, impairment

CBF = cerebral blood flow; CMRO₂ = cerebral metabolic rate of oxygen.

of CMRO₂ directly correlated with the duration of unprotected CA (Fig 2). Regression analysis of this relationship predicts that at 18°C, the percent recovery of CMRO₂ = $(-0.86)(\text{CA duration}) + 97$; ($r^2 = 0.73$; $p = 0.0001$). By contrast, systemic oxygen consumption recovered to Pre values in all groups.

Topical cooling of the head during 60 minutes of CA significantly improved recovery of CMRO₂ as compared with 60 minutes of CA without topical cooling. In animals treated with trickle-flow, CMRO₂ fully recovered to Pre values. Figure 3 illustrates the efficacy of these protective measures as demonstrated by percent recovery of CMRO₂. In addition to CMRO₂, CBF and cer DO₂ were also reduced after CA. However, cer a-vO₂ and the cerebral oxygen extraction ratio were unchanged from Pre values in all groups.

Comment

The "Safe" Duration of Circulatory Arrest

Relative to other organs in the body, the brain's metabolic requirement for oxygen is high and its tolerance to ischemia is low. This is the obvious limitation to CA. To achieve "safe" CA, hypothermia is used to reduce, but not eliminate, the cerebral demand for oxygen during the period that oxygen supply is unavailable. Data from this study (see Tables 1, 2) reinforce the fact that in spite of cooling to 18°C, over 30 minutes, cerebral requirements for oxygen persist at a significant level when CA is initiated. Others have documented similar findings. In the laboratory setting, CMRO₂ in dogs at 20°C remained 35% to 40% of normothermic values immediately before CA [5, 6]. Clinically, data from our institution also confirm that CMRO₂ in infants remains significant at the time circulatory arrest is initiated [7].

The true safe interval for hypothermic CA ends at that time when the demand for oxygen is unfulfilled and some degree of ischemia ensues. The present study suggests that a measurable impairment of cerebral metabolic function may occur within minutes of beginning hypothermic CA. As shown in Table 2, recovery of CMRO₂ was significantly reduced after only 15 minutes of CA. However, CBF was unchanged over the same period. There-

fore, impairment of CMRO₂ is likely due to one or both of the following mechanisms: redistribution of blood flow away from oxygen-consuming cells or a primary inability to utilize delivered oxygen. Aoyagi and associates [8] and Hossmann and colleagues [9] have both demonstrated substantial changes in regional cerebral blood flow after hypothermic CA. Perna and co-workers [6] performed continuous measurements of cerebral cortical tissue oxygen tension and observed a rapid depletion of oxygen tension immediately after initiation of CA. Utilization of oxygen by the brain ceased within the first 15 minutes of the arrest period.

The CA-induced metabolic impairment noted at hypothermia continued after rewarming to 37°C and weaning off bypass (see Table 3). At Pre and Post measurements, systemic blood flow was pulsatile, and mean arterial blood pressure and systemic cardiac output did not differ significantly in any group. In control animals, postbypass CMRO₂ recovered fully to baseline values. In animals receiving CA, postbypass CMRO₂, CBF, and cer DO₂ were all lower when compared with Pre values. However, cer a-vO₂ and cer O₂ Extraction were unchanged in these groups, and therefore the impairment of CMRO₂ was not due to limitation of global oxygen delivery.

Contrary to perceptions that CA is physiologically inconsequential until 30 to 45 minutes, this study defined a linear relationship between duration of CA and impairment of cerebral metabolism (see Fig 2). Impairment of cerebral metabolism begins immediately and becomes progressively worse as the duration of circulatory arrest lengthens. A similar relationship was described by Fisk and colleagues [10, 11], who studied neonatal piglets with electroencephalography before, during, and after variable periods of CA at 20°C. Results demonstrated that electroencephalographic activity ceased within seconds of CA and that return of electroencephalographic activity was significantly delayed as compared with several sets of controls. Most importantly, the delay in return of electroencephalographic activity was linearly related to the duration of CA. Histologic specimens obtained 10 days after CPB found consistent lesions in the cerebral cortex of CA animals that were identical to lesions found in control animals subjected to 5 minutes of warm anoxia.

$$\% \text{ Recovery CMRO}_2 = (-0.86 \times \text{CA Duration}) + 97$$

$$r^2 = 0.73$$

Fig 2. Percent cerebral metabolic rate of oxygen (CMRO₂) recovery versus duration of circulatory arrest: Least-squares regression of percent recovery of cerebral metabolism versus duration of circulatory arrest (CA) demonstrated a linear relationship with $r^2 = 0.73$ ($p = 0.0001$). This relationship is predicted by the formula: %Recovery CMRO₂ = $(-0.86 \times \text{CA duration}) + 97$.

These patterns of responses reflect measurable metabolic and histologic changes that occurred immediately after CA and continued after weaning from bypass. However, correlates between structural injury and functional sequelae are also important. Clinical studies conducted at our institution are consistent with these laboratory findings [7]. In this study of 46 pediatric patients receiving hypothermic CPB, cerebral metabolism and oxygen extraction were significantly reduced during rewarming and after bypass and suggested disordered cerebral metabolism and oxygen utilization after deep hypothermic CA. The results of other clinical studies that included long-term follow-up are mixed [12-14].

Cerebral Protection

Having defined the relationship between CA duration and metabolic impairment, methods of cerebral protection were objectively evaluated. Topical cooling of the head is routinely used at several institutions. In this investigation, topical cooling of the head ameliorated the metabolic impairment of 60 minutes of CA. This benefit was most likely due to further reduction of the cerebral oxygen requirements by cooling the head to an average of 12.6°C, thereby delaying the time to ischemia. Packing the head in ice can be performed without difficulty in the clinical setting, and is recommended for CA. Although regional metabolism of other organs was not measured, systemic oxygen consumption recovered fully after circulatory arrest at 18°C.

Recent data suggest that hypothermia causes changes

Fig 3. Efficacy of protective strategies on percent cerebral metabolic rate of oxygen (CMRO_2) recovery: Topical cooling by packing the head in ice reduced nasopharyngeal temperature to 12.6°C during 60 minutes of circulatory arrest (CA). This intervention demonstrated a clear improvement in recovery of cerebral metabolism as compared with 60 minutes of CA without topical cooling. More dramatically, CMRO_2 recovery was greater than 90% when trickle-flow cardiopulmonary bypass was maintained at 5 to $10 \text{ mL} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$ at 18°C for 60 minutes. (CTL = control; groups are defined in Figure 1.)

at the cellular level that may enhance tolerance of ischemia [15]. This has led some investigators to explore the use of extreme hypothermia (less than 10°C) to extend the "safe" period of CA to 90 to 180 minutes [16, 17]. Further study will be required to determine the safety of these exceptionally low temperatures.

Continuous, low (trickle) flow also demonstrated efficacy for cerebral protection in this study. With perfusion at 5 to $10 \text{ mL} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$ and 18°C for 60 minutes, cerebral metabolism fully recovered after CPB. This flow rate was chosen to simulate the clinical setting where the minimum sustainable flow from a $\frac{1}{4}$ -inch raceway in a standard roller pump head is 5 to $10 \text{ mL} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$. Other investigators have also studied various low-flow perfusion strategies. Miyamoto and colleagues [18] recommended an optimal perfusion flow rate of $30 \text{ mL} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$, whereas Swain and associates [19] maintained high-energy phosphate concentrations with flow rates of $10 \text{ mL} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$. Others [20] have successfully combined pulsatile blood flow with low-flow perfusion. Studies of regional perfusion during low-flow hypothermic perfusion indicate that all areas of the brain remain perfused [21]. Hypothermic low-flow perfusion combines a reduction of oxygen requirement with continued oxygen delivery and provides superior protection of the brain by minimizing the potential for cerebral ischemia. It is recommended when technically feasible.

This investigation describes a pattern of cerebral metabolic response to varying periods of ischemia at 18°C and provides an objective set of indices that should permit evaluation of new cerebral protective strategies. Clinical studies at our institution have been performed using these measurement techniques and experimental protocols with similar results. Therefore, the animal model used in this study encourages further investigation of specific questions related to cerebral protection with the expectation that the results will be clinically relevant.

This study was supported, in part, by the Public Health Service, National Institutes of Health, National Research Service Award HL08351 and the Duke Miracle Network Telethon Fund.

We thank Dr Frank H. Kern and Dr R. Lawrence Reed III for their assistance in this investigation.

DISCUSSION

DR JULIE A. SWAIN (Las Vegas, NV): Several years ago we also used nuclear magnetic resonance spectroscopy to look at low flows. I wonder why you chose 5 to 10 mL · kg⁻¹ · min⁻¹. We showed that 10 mL · kg⁻¹ · min⁻¹ was great and that 5 mL · kg⁻¹ · min⁻¹ was minimally protective. Is there not some work from your institution to suggest exactly what the lower limit of flow should be?

DR MAULT: We are very aware of your significant contributions to this field. Our flow rate of 5 to 10 mL · kg⁻¹ · min⁻¹ was selected as the minimum amount of flow that could be used during this period to facilitate a clear operative field and yet at the same time provide cerebral protection. We recognize that your data using nuclear magnetic resonance showed a less than optimal response with 5 mL · kg⁻¹ · min⁻¹. However, we think that there may be some benefit during 60 minutes of circulatory arrest.

DR SWAIN: My other question is on your venous oxygen saturation data. Can we assume that one might be able to monitor cerebral venous oxygen saturation, because that is relatively easy to do versus xenon or microspheres, to see adequacy of oxygen delivery and how we might affect delivery in the postoperative period?

DR MAULT: Measurement of venous saturation is a reliable reflection of oxygen consumption and delivery relationships; however, there is a contrast between these data and the data that were just presented in that we saw no change in the arterio-venous oxygen extraction ratio. What actually happened in this series of data is that the cerebral blood flow also went down in parallel with the cerebral metabolic rate, and therefore the extraction ratio did not change. In that situation the sagittal sinus saturations would not reflect the impairment.

DR JOHN C. ALEXANDER, JR (Evanston, IL): I enjoyed your report. I would like to make a comment and then offer a suggestion. The models that we have seen today are interesting. They mimic the pediatric group of patients who are treated with hypothermic arrest in that the aorta is closed. If the aorta is closed you can use the antegrade "trickle" technique that Paul Ebert popularized. I think the information you have shown is really quite good to document its importance and usefulness.

In the adult patient, when we are faced with aortic reconstructions, we almost always are working on an open aorta. There are some interesting technical differences when the aorta is open in that the potential for air embolization and debris embolization is present. We have used the trickle technique but have used it differently in the adult setting. We pump backward into the right atrium at the trickle flow rate and are able to see blood coming retrograde out of the head vessels. We think we accomplish the same thing in a practical sense. We have done this in 10 patients

and have not had any neurologic problems in some extended periods of aortic reconstruction. I would suggest you try this model with the aorta open and use the reverse trickle technique. Somehow the blood finds its way back through the brain. We have measured the oxygen content as blood comes out of the head vessels and it is really very low compared with the oxygen content of blood going into the right atrium. This technique also provides excellent myocardial protection; it gives you retrograde cardioplegia, if you will.

DR MAULT: Thank you very much. I am quite excited about that suggestion. In fact, in the laboratory at this time we are currently performing studies to follow up on what the mechanism of this protection might be, and I agree with you wholeheartedly that some minimum perfusion of the brain may be simply clearing the metabolic wastes, the acids, whatever, that may be building up during the circulatory arrest period, and that accomplishing this by whatever means may be protective.

DR ALEXANDER: I think there are a couple of other things you can say about this technique. First, it will maintain the hypothermic temperature of the brain better than you can do with topical cooling, and second, it prevents air locks from getting into the brain. If you watch what happens when you open the aorta and still have your venous reservoir open, you see blood followed by air sucked through the venous cannula. I think you create air locks in the brain. The first report that was presented showed a vulnerable period that becomes very important. It is during that period that the air locked spots in the brain do not get perfused and are damaged.

DR RANDALL B. GRIEPP (New York, NY): I have one comment, and then I should like to ask you to respond to two discrepancies between your studies with the piglet model and ours with the dog. The comment is that I am delighted to see experimental data supporting the fact that topical cooling of the head is important. I think that in many cases of neonatal surgery and aneurysm surgery the head has not been packed in ice during the period of circulatory arrest, and unnecessary cerebral damage has resulted.

The two discrepancies between your studies and ours are, first, that after 45 or 90 minutes of circulatory arrest, we do not see any significant fall in cerebral metabolic rate for oxygen in the postbypass period as compared with the normothermic control. We do, however, see remarkably reduced cerebral blood flow with maintenance of normal CMRO₂ by increased oxygen extraction. As I understand it in your animals there is almost always some degree of reduction in cerebral metabolic rate for oxygen in the early postbypass period. Second, perhaps you could comment on the difference in the basal cerebral metabolic rate for oxygen. In our weanling puppies, using microspheres to measure blood flow, cerebral metabolic rates for oxygen vary between

3.5 and 5 mL/100 g of brain per minute in the normothermic anesthetized state. In your piglets the corresponding figure, as I understand, it is approximately 1.5 to 2 mL/100 g of brain tissue per minute.

DR MAULT: Thank you very much. There is definitely some disparity between these two models, however, we are measuring these parameters at two different time points, and it very well

may be that CMRO₂ recovered fully if this is measured 2 hours after bypass. In our study, post measurements were taken at 30 minutes immediately after stabilization off bypass, and that may be a factor. There is also a species difference that certainly has to be considered, and at the same time, within our species of piglet model, these CMRO₂ values and the cerebral blood flows are both consistent with piglet studies of this type that have been conducted by Fisk and others over the last 20 years.

Notice From the American Board of Thoracic Surgery

The part I (written) examination will be held at the Hilton Executive Conference Center, Dallas Fort Worth Airport, Dallas, TX, on February 13, 1994. The closing date for registration is August 1, 1993.

To be admissible for the part II (oral) examination, a candidate must have successfully completed the part I (written) examination.

A candidate applying for admission to the certifying examination must fulfill all the requirements of the board in force at the time the application is received.

Please address all communications to the American Board of Thoracic Surgery, One Rotary Center, Suite 803, Evanston, IL 60201.

Improved Multiorgan Function After Prolonged Univentricular Support

Clay M. Burnett, MD, J. Michael Duncan, MD, O. H. Frazier, MD,
Michael S. Sweeney, MD, J. David Vega, MD, and Branislav Radovancevic, MD

Transplant Service, Texas Heart Institute/St. Luke's Episcopal Hospital; and University of Texas Medical School at Houston, Houston, Texas

Eleven cardiac transplant candidates (all male; mean age, 43.3 years) with multiorgan (hepatic, pulmonary, and/or renal) dysfunction were sustained for prolonged periods (>30 days) with the HeartMate (Thermo Cardiosystems, Inc, Woburn, MA) left ventricular assist device. We evaluated the effect of extended support on end-organ recovery and on the ultimate outcome of cardiac transplantation. In addition to cardiac failure, 9 patients had hepatic dysfunction, 8 had pulmonary dysfunction, and 6 had renal dysfunction (4 of whom required hemodialysis before left ventricular assist device support). Mean duration of support was 115 days (range, 31 to 233 days). All patients underwent successful transplantation; 10 of these patients survived a mean of 24 months. One patient, who had required hemodialysis and ventilatory support during and after support, experienced progressive multiorgan failure and died 7 weeks after transplan-

tation. Two late deaths after transplantation were unrelated to the device. Overall, patients experienced improvement in cardiac functional class status, and most participated in cardiac rehabilitation programs before transplantation. During left ventricular assist device support, hepatic function returned to normal in 8 patients, pulmonary function recovered in 7, and renal function returned to normal in 4. One patient who required hemodialysis underwent renal transplantation after cardiac transplantation and had complete recovery of renal function. In the current era of donor shortages, gravely ill patients can benefit from a strategy of prolonged left ventricular assist device support. This strategy has proved safe, has allowed for reversal of multiorgan dysfunction, and has produced healthier transplant candidates.

(*Ann Thorac Surg* 1993;55:65-71)

A variety of circulatory support devices have proved effective for the temporary support of patients awaiting cardiac transplantation [1-3]. The benefits of circulatory support in patients being bridged to transplantation, however, are often limited by the increased risks from device-related complications [4]. Consequently, many centers favor shorter periods of mechanical circulatory assistance, and patients undergo transplantation as soon as possible [5, 6]. Some of these patients experience multiorgan dysfunction either before or during the time of support and are not necessarily optimal transplant candidates [2, 3, 5]. Unfortunately, many such patients are excluded from the benefits of cardiac transplantation on the basis of impaired end-organ function, despite an overall survival rate that is comparable with that in transplant recipients who did not require any form of mechanical assistance before the operation [2, 6, 7].

Extended mechanical support has been shown to result in improved end-organ function and to create a healthier recipient candidate [3, 8, 9]. In clinical studies that have been ongoing at our institution for more than 5 years, the HeartMate (Thermo Cardiosystems, Inc, Woburn, MA) left ventricular assist device (LVAD) has been used suc-

cessfully during periods of prolonged support and has proved both safe and reliable [10, 11]. Evidence from this experience suggests that prolonged support may be beneficial because of the significant delay between improvement in post-LVAD hemodynamic function and subsequent end-organ recovery. To assess the effect of extended support in potential recipients with multiorgan dysfunction, we evaluated 11 patients who required prolonged support (>30 days) before cardiac transplantation and determined its impact on end-organ recovery and on the ultimate outcome of cardiac transplantation.

Patients and Methods

Of the 328 patients who have undergone cardiac transplantation at the Texas Heart Institute since 1986, 18 (5.5%) required an LVAD as a bridge to transplantation. Eleven of these patients (3.3%) were supported for more than 30 days before a suitable donor heart was obtained. To determine the effects of prolonged LVAD support on end-organ function, we examined indices of hepatic, pulmonary, and renal function in these 11 patients before and during LVAD assistance.

All of the patients were male (mean age, 43.3 years; range, 22 to 55 years). Each patient was receiving maximal pharmacologic support with various combinations of vasoactive medications (ie, dopamine, dobutamine, amrinone, epinephrine, or norepinephrine) at the time of

Presented at the Thirty-eighth Annual Meeting of the Southern Thoracic Surgical Association, Orlando, FL, November 7-9, 1991.

Address reprint requests to Dr Frazier, Texas Heart Institute, PO Box 20345, Houston, TX 77225-0345.

LVAD placement. Eight of the patients were treated with the HeartMate after intraaortic balloon pump therapy, and the remaining 3 patients required LVAD placement on an urgent basis, before treatment with the intraaortic balloon pump was attempted. The indication for cardiac transplantation was either ischemic (5 patients) or idiopathic (6 patients) cardiomyopathy. Only one patient in this series had undergone a previous cardiac operation.

Gated nuclear scan studies were done in all patients before LVAD insertion. The average left ventricular ejection fraction was 0.17 (range, 0.08 to 0.26), and the average right ventricular ejection fraction was 0.21 (range, 0.12 to 0.27).

Implantation of the HeartMate was restricted to patients who had been approved for cardiac transplantation and who met specific treatment criteria: inotropic support, intraaortic balloon pump support (if possible), and left atrial pressure or pulmonary capillary wedge pressure greater than 20 mm Hg with systolic blood pressure less than 80 mm Hg or cardiac index less than $2.0 \text{ L} \cdot \text{min}^{-1} \cdot \text{m}^{-2}$. Patients who met the criteria and who were considered to have reversible hepatic, renal, or pulmonary dysfunction were considered acceptable for undergoing prolonged support.

Hepatic dysfunction was defined as a serum total bilirubin concentration greater than $34.2 \mu\text{mol/L}$ (2.0 mg/dL) or a serum glutamic-oxaloacetic transaminase concentration greater than 500 IU/L. Renal dysfunction was defined as an increase in serum creatinine level to greater than $176.8 \mu\text{mol/L}$ (2.0 mg/dL) or an increase in blood urea nitrogen level to greater than 14.3 mmol/L (40 mg/dL), with recent onset of severe oliguria or anuria despite diuretic administration. Our definition of renal dysfunction also included the need for hemodialysis as a result of cardiac failure before LVAD insertion or at any time after cardiac transplantation. A patient was considered to have pulmonary dysfunction when mechanical ventilatory support was needed before operative intervention, when radiographic evidence of severe pulmonary edema was present, or when major respiratory limitations to even mild exercise were present.

Improvement in cardiovascular function was assessed by comparing hemodynamic indices just before LVAD insertion and after 72 hours of LVAD support. Improvement in hepatic function was measured by comparing total bilirubin concentration and serum glutamic-oxaloacetic transaminase level, as well as other biochemical measures of hepatic function (serum glutamic-pyruvic transaminase level and prothrombin time), before instituting support and at the time of transplantation. Renal function was similarly evaluated by comparing serum markers (creatinine and blood urea nitrogen levels), the presence of oliguria ($<0.5 \text{ mL} \cdot \text{kg}^{-1} \cdot \text{h}^{-1}$), or the requirement for hemodialysis before LVAD insertion and at the time of transplantation. Pulmonary function was assessed by comparing serial chest radiographs obtained before and after LVAD implantation, the need for prolonged mechanical ventilation, and the recovery of respiratory function in response to exercise.

All patients had been approved by the St. Luke's

Fig 1. Summary of experience in 11 patients with multiorgan dysfunction who required prolonged (>30 days) left ventricular assist device support as a bridge to transplantation (Tx).

Episcopal Hospital Medical Review Board for cardiac transplantation and were on the active transplant waiting list before LVAD insertion. Informed consent was obtained before LVAD insertion, and all other Institutional Review Board guidelines were followed.

Device Description

The HeartMate LVAD is a pneumatically actuated, abdominally positioned LVAD that consists of a pulsatile pusher-plate blood pump within a rigid titanium housing [10]. All blood-contacting surfaces, except the 25-mm porcine xenograft valves within the inlet and outlet conduits, are textured with either sintered-titanium microspheres or integrally textured polyurethane [12], and these surfaces promote the formation of a biologic lining. The device has a maximum stroke volume of 85 mL and is capable of providing blood flows up to 10 L/min. The techniques for device implantation have been described [13].

Postoperative Management

To reduce the incidence of infections after LVAD implantation, oximetric pulmonary artery catheters and chest tubes were usually removed within 72 hours of the implant operation. Dextran was administered in the early postoperative period and was converted to low-dose aspirin and dipyridamole when the patient resumed oral intake. Early after operation, patients were encouraged to become mobile, and they usually began a cardiac rehabilitation program (stationary bicycling, walking, and treadmill exercise) by the second week after implantation.

Results

All 11 patients survived LVAD implantation and underwent cardiac transplantation. Mean survival in 10 of the patients was 24 months (range, 49 days to 44 months) (Fig 1). The mean duration of LVAD support was 115 days (range, 31 to 233 days). All but 1 patient received orthotopic cardiac transplants; heterotopic cardiac transplantation was performed in the first patient because of elevated pulmonary vascular resistance.

Table 1. Effects of Prolonged (1,269 days) Left Ventricular Support on End-Organ Function

Functional Index	Mean Level Before Implantation (range)	Mean Level at Explantation (range)
Cardiovascular		
Cardiac index ($L \cdot min^{-1} \cdot m^{-2}$)	1.83 (1.3-2.78)	3.43 (2.2-5.1)
Pulmonary artery pressure (mm Hg)	34.1 (18-50)	27.6 (16-39)
Pulmonary capillary wedge pressure (mm Hg)	26.0 (7-40)	11.1 (5-20)
Central venous pressure (mm Hg)	14.9 (8-25)	12.4 (6-21)
Hepatic		
Total bilirubin (mg/dL)	4.4 (1.5-10.9)	1.6 (0.4-10.5)
SGOT (mg/dL)	1,233 (32-9,549)	52.3 (22-179)
SGPT (mg/dL)	756 (17-7,345)	70.7 (17-311)
Prothrombin time (s)	13.8 (11.5-18.5)	12.0 (11.0-14.0)
Renal		
Blood urea nitrogen (mg/dL)	59.3 (17-132)	29.3 (13-90)
Serum creatinine (mg/dL)	3.1 (1.1-9.3)	1.5 (0.7-1.7)

SGOT = serum glutamic-oxaloacetic transaminase; SGPT = serum glutamic-pyruvic transaminase.

All 11 patients were in New York Heart Association functional class IV before LVAD implantation despite aggressive medical management. In addition to end-stage heart failure, each patient was experiencing impaired function of at least one other organ before LVAD insertion: 5 patients had evidence of impaired function of three other organs, 3 patients had impaired function of two other organs, and 3 patients had impaired function of one other organ. Altogether, 9 patients had hepatic dysfunction, 8 had pulmonary dysfunction, and 6 had renal dysfunction.

One patient, the first in this series to undergo treatment with the HeartMate, died as a result of systemic candidiasis and cytomegalovirus infection 7 weeks after cardiac transplantation. Hepatic, renal, and pulmonary dysfunction did not recover during LVAD support, and progressive multiorgan failure occurred despite aggressive systemic antibacterial and antifungal therapy. Postmortem examination revealed cirrhosis, in addition to systemic candidiasis and multiorgan failure. Two late deaths occurred: 1 patient died suddenly 34 months after transplantation, the suspected cause being noncompliance with the immunosuppressive regimen, and the other patient died of severe coronary atherosclerosis 29 months after transplantation.

Cardiovascular Function

All hemodynamic indices improved within 24 hours of LVAD insertion. Indices of cardiac function were documented after 72 hours of LVAD support and then compared with those obtained before support was initiated (Table 1). In each patient, a striking improvement was noted in the mean cardiac index (Fig 2), mean pulmonary artery pressure, and pulmonary capillary wedge pressure. The mean central venous pressure was slightly reduced during support. After 30 days of mechanical circulatory support, the cardiac status of all patients had improved: 8 patients were in functional class I, and 3 patients, including the first one in this series, were in functional class II.

Hepatic Function

Nine patients had hepatic dysfunction before LVAD support, and hepatic function had returned to normal in 8 (89%) by the time of LVAD removal. Improvement was reflected by markedly decreased bilirubin (total and direct) levels (Fig 3A), as well as serum glutamic-oxaloacetic and glutamic-pyruvic transaminase levels (Fig 3B). The only patient who did not recover normal hepatic function was the one who died of multiorgan failure in addition to chronic liver cirrhosis. Overall, the biochemical indices representing hepatic function in 10 patients showed marked improvement with prolonged support (see Table 1).

Pulmonary Function

Pulmonary function recovered in 7 of 8 patients who had required mechanical ventilation before LVAD insertion.

Fig 2. Improvement in cardiovascular function, as evidenced by comparison of cardiac index measurements obtained just before left ventricular assist device (LVAD) implantation and 72 hours after initiation of support.

B

Fig 3. Improvement in hepatic function, as evidenced by total and direct bilirubin levels (A) and by serum transaminase levels (B). Measurements were obtained just before left ventricular assist device (LVAD) implantation, and just before LVAD explantation. (SGOT = serum glutamic-oxaloacetic transaminase; SGPT = serum glutamic-pyruvic transaminase)

The 7 patients who experienced pulmonary improvement were easily weaned from mechanical ventilation after LVAD implantation. The average time between LVAD implantation and the withdrawal of ventilatory support in 10 of the 11 patients was 4.3 days (range, 1 to 20 days). Five patients were extubated within 48 hours of LVAD insertion, and 3 patients were extubated between 72 and 96 hours; 2 patients required prolonged ventilatory support (10 and 20 days after implantation). The remaining patient, the first patient in this series to undergo treatment, was briefly extubated on several occasions after LVAD implantation and after cardiac transplantation, but each time he required reintubation because of deteriorating mental status and progressive multiorgan failure.

Signs of pulmonary edema were apparent in 6 of the 11 patients before LVAD insertion (Fig 4A). Despite the rapid clinical improvement in respiratory function that allowed early withdrawal of mechanical ventilation, all 6 patients had radiographic evidence of pulmonary edema that persisted for several weeks. Complete resolution of pulmonary edema in all of these patients was seen radiographically within 4 weeks of initiating LVAD support (Fig 4B).

A

B

Fig 4. Improvement in pulmonary function, as evidenced by a representative chest radiographic series. The first chest radiograph was obtained just before left ventricular assist device implantation (A), and the second was obtained just before left ventricular assist device explantation (B).

Before undergoing mechanical support, all 11 patients were confined to bed because of severe dyspnea. By the end of the second week after LVAD insertion, 6 were walking independently, and by 4 weeks, 9 were participating in vigorous cardiac rehabilitation programs.

Renal Function

Four of the 6 patients who had renal dysfunction before LVAD implantation had undergone prior hemodialysis (see Table 1). Three additional patients in whom signs of impending renal dysfunction were present (severe oliguria or anuria) underwent urgent LVAD insertion before serious elevation in blood urea nitrogen or serum creati-

Fig 5. Improvement in renal function, as evidenced by blood urea nitrogen (BUN) and serum creatinine levels. Measurements were obtained just before left ventricular assist device (LVAD) implantation and just before LVAD explantation.

nine levels occurred. After extended LVAD support, all 11 patients exhibited a decline in azotemia, although two remained dependent on hemodialysis. Altogether, the mean blood urea nitrogen level decreased to 10.5 mmol/L (29.5 mg/dL) (range, 4.6 to 32.1 mmol/L [13 to 90 mg/dL]), and the mean serum creatinine level dropped to 132.6 μ mol/L (1.5 mg/dL) (range, 61.9 to 203.3 μ mol/L [0.7 to 2.3 mg/dL]) (Fig 5). When the 2 patients who continued to require hemodialysis were excluded from this analysis, however, the mean blood urea nitrogen and serum creatinine levels after extended LVAD support were even lower, at 6.7 mmol/L (18.9 mg/dL) and 106.1 μ mol/L (1.2 mg/dL), respectively.

In addition to being azotemic, 9 patients were oliguric before LVAD support, 7 of whom had severely diminished urinary outputs. After prolonged LVAD support, urinary outputs returned to normal in 8 patients, including 3 of the 4 patients who needed hemodialysis before LVAD support was initiated. Two of the 3 patients recovered normal renal function with prolonged mechanical support, and hemodialysis was discontinued.

Of the 2 patients who remained dependent on hemodialysis despite prolonged mechanical support, 1 underwent cardiac transplantation, followed by renal transplantation. After renal transplantation, the patient had complete recovery of renal function. The other patient (again, the first patient in this series to undergo treatment) remained on hemodialysis until the time of his death.

Comment

Although cardiac transplantation is now an accepted therapeutic option for the treatment of end-stage heart disease, the scarcity of suitable donor organs suggests that many potential recipients may require some form of mechanical circulatory support before transplantation [3, 4]. Indeed, of the 16,687 patients listed in the International Registry for Heart Transplantation who had received primary cardiac allografts worldwide through January 1, 1991, 363 (2%) had been bridged to transplantation

with either a ventricular assist device or a total artificial heart [6, 14]. The need for pretransplantation circulatory assistance within the United States may be even higher, ranging between 13% and 29% at some centers [1, 7]. As the long-term survival rates for patients undergoing bridged transplant procedures are beginning to approach that of patients undergoing traditional cardiac transplant procedures, a strategy combining mechanical support with cardiac transplantation appears to be justified [6, 7, 9, 15-18].

The primary emphasis in many bridge-to-transplantation programs has been to support device-dependent patients until the first donor organ becomes available [2, 3, 6, 8]. Unfortunately, many heart transplant candidates who are bridged to transplantation have development of multiorgan dysfunction that can limit, or even preclude, successful cardiac transplantation [1, 2, 4]. Early transplantation for these gravely ill patients may not be optimal, because end-organ recovery often lags substantially behind any improvement noted in hemodynamic function after LVAD placement [11]. Although a few centers [3, 8, 9] have noted improvement in end-organ function with longer periods of support, there have been no clinical trials justifying the selective use of long-term support for patients with multiorgan dysfunction.

In the past, the complications of stroke, thromboembolism, and bleeding associated with mechanical circulatory assist devices limited the ability to provide long-term support and to effect improved multiorgan function. The HeartMate not only provides adequate systemic circulation, but also minimizes the risk of thromboembolic complications through the use of textured blood-contacting surfaces, which promote deposition of a stable, biologic lining [11]. Only 1 patient, who was treated at another institution, has experienced a thromboembolic complication [19], which was attributed to a mechanical valve in the native heart, and these results have been achieved despite minimal anticoagulation with aspirin and dipyridamole.

In addition to having reduced thrombogenicity, patients treated with the HeartMate have remained remarkably free from serious infectious complications. Other prosthetic devices that are positioned orthotopically, such as total artificial hearts, do not fill the pericardium, leaving room for potential mediastinal infections. We believe that placing the pump extrathoracically has helped to lower the incidence of infectious complications and to eliminate the potential for mediastinal infections. After abdominal placement, a tissue capsule forms around the pump, similar to the capsule that forms around a pacemaker. The only infections noted in this series occurred at the drive line site, and these responded to local wound care and short-term antibiotic therapy.

Our study demonstrates that prolonged LVAD support in patients bridged to cardiac transplantation can improve organ function if support is initiated before the onset of irreversible organ failure. The 11 patients in the current study had a total of 23 impaired organ systems before LVAD insertion, and function improved in all but four organ systems, three of which were in the first patient in

the series (who died of progressive multiorgan failure). The remaining patient had impaired renal function, but this did not prohibit successful LVAD support or cardiac transplantation. This patient, in fact, underwent uncomplicated renal transplantation approximately 2 months after cardiac transplantation. Although he subsequently died of progressive cardiac allograft atherosclerosis, the remainder of his posttransplantation course was unremarkable.

All 11 patients regained normal hemodynamic function after implantation of the HeartMate, with most experiencing an improvement to functional class I status. The improvement in hemodynamic indices occurred almost immediately after LVAD insertion, and within 2 weeks, the majority of patients were actively engaged in cardiac rehabilitation programs. Recovery of normal end-organ function, however, appears to be slower, and several weeks may pass before functional indices normalize.

Hepatic function improved in all but 1 patient after LVAD support was initiated. Unfortunately, the mechanisms responsible for the improvement in hepatic function remain elusive [20-22]. Because passive venous congestion and hepatic arterial hypoperfusion both appear to contribute to ischemic liver injury [23, 24], it appears that in the absence of elevated pulmonary vascular resistance, left ventricular assistance can adequately provide effective relief of right heart congestion, as well as improve hepatic arterial perfusion [25, 26]. Whether relief of venous congestion or improvement in arterial perfusion was more important cannot be ascertained in this small series.

In contrast to others [2], we have not excluded patients in renal failure from the benefits of mechanical circulatory support or cardiac transplantation. Our current results indicate that impaired renal function does not necessarily affect the interval of LVAD support or the outcome of cardiac transplantation. Reversal of azotemia and oliguria can be expected if support is initiated early and if support is able to be maintained long term [9]. Moreover, even patients who fail to recover renal function despite long-term LVAD support can safely undergo chronic dialysis and can ultimately undergo transplantation.

Despite the delayed clearance of pulmonary edema on chest radiographs, pulmonary function appears to improve early after institution of LVAD support. In the majority of patients in this series, rapid withdrawal of mechanical ventilation was possible, and progressive improvement in exercise tolerance occurred. The response of pulmonary function to LVAD support under conditions of preexisting disease, such as chronic obstructive disease, reactive airway disease, or previous pulmonary resection, may be less favorable. Nonetheless, the rapid improvement in pulmonary function with prolonged LVAD support in 8 of 11 patients who required mechanical ventilation preoperatively strongly supports the concept of univentricular support in patients with pulmonary dysfunction caused by severe heart failure.

Despite extended LVAD support, the first patient in this series died of multiorgan failure as a result of opportunistic infection in the posttransplantation period. Failure to recover hepatic, renal, and pulmonary function, the

inability to resolve persistent systemic fungal infections, and, ultimately, the progression to fulminant multiorgan failure strongly implied that the onset of irreversible organ failure had already occurred by the time of LVAD implantation. This was confirmed by postmortem examination, which revealed cirrhosis, in addition to progressive multiorgan failure. Our subsequent practice has been to assess serious preoperative hepatic dysfunction with transvenous liver biopsy [27]. Histopathologic evidence of fibrotic cirrhosis in biopsy specimens is now regarded as a contraindication to LVAD support and cardiac transplantation.

In conclusion, for patients with end-organ dysfunction that is refractory to maximal medical therapy and intraaortic balloon pump support, intervention with LVAD support can lead to the recovery of normal function. True recovery may, in fact, require prolonged periods of mechanical circulatory support, and this technology is currently available. The restoration of health granted with such support clearly improves one's chances of a smooth posttransplantation course. We have found that prolonged univentricular support is achievable and safe and that it has real efficacy in promoting the successful use of a donor heart in this era of donor organ shortages.

DISCUSSION

DR J. ALEX HALLER, JR (Baltimore, MD): Dr Burnett, one of the fascinating things about your report is that you are focusing on end organs that can be studied, but the main cause of death in patients with multiple organ failure is sepsis. Did you look at blood cultures during this period? The dramatic thing to me is that you did not have more problems with infection in this group of patients, only 1 I believe you said, who ultimately died of overwhelming infection. Were there decreases in the number of patients with bacteremias, because it is the gut with its translocation that seems to be the main cause of death in this group of patients, and yet that seemed to be reversed with the use of the LVAD.

DR BURNETT: Although the reduced incidence of sepsis in our study group involves many factors, we believe that initiating circulatory support early and maintaining it until end-organ function improves are the main reasons. Using mechanical assistance before irreversible end-organ damage occurs cannot be overemphasized, as evidenced by our previous study in which transplant candidates who had chronic nutritional depletion and end-organ failure underwent early treatment with the HeartMate LVAD. Prolonged support improved visceral protein status, restored serum albumin levels and transferrin levels, and normalized body fat distribution. In addition, use of the HeartMate allowed early resumption of oral food intake and, thus, a return to normal gut function. Consequently, bacterial translocation through attenuated intestinal mucosal barriers is reduced, and, as a result, systemic sepsis may be prevented.

In contrast, the 1 patient who died as a result of sepsis and who was the first to undergo treatment had support initiated late in his course, after end-organ failure was firmly established.

Finally, when LVAD support is initiated early, we have found that virtually all patients with reversible organ dysfunction will return to New York Heart Association class I status, which greatly improves their ability to withstand transplantation.

DR ROBERT A. ALBUS (Fairfax, VA): I wonder if you could comment on the current status of your totally implantable device that you have in. I think it is still functioning now, right?

DR BURNETT: The patient you refer to is a 33-year-old man with severe idiopathic cardiomyopathy who had the electrically actuated LVAD implanted in September 1991. He has been supported by the device for 8½ weeks and has already returned to New York Heart Association class I status. The patient, who carries an 8-hour battery pack in a shoulder harness, is walking and exercising, and he is in better condition now than he had been during the previous 2 years.

The main components of the pneumatic- and electric-powered LVADs are the same, except that a 14F compliance vent and an electric cable have been added to the latter device. Thus, we anticipate that our clinical results with the electric pump will also be positive. Our experience with the pneumatic device and the successful conversion to electrical actuation has excited us in that we may have a model prototype for future permanent implantation.

Component Analysis of Bilateral Anterior Cardiomyoplasty

Anthony P. Furnary, MD, James A. Magovern, MD, Ignacio Y. Christlieb, MD, Dennis R. Trumble, and George J. Magovern, MD

Department of Surgery, Allegheny General Hospital; Surgical Research, Allegheny-Singer Research Institute; and Medical College of Pennsylvania, Pittsburgh, Pennsylvania

This experiment was designed to analyze the mechanism of ventricular augmentation generated with bilateral anterior cardiomyoplasty by comparing it in an acute setting with its components, the left anterior cardiomyoplasty and the right anterior cardiomyoplasty. Hemodynamic variables were measured in 8 dogs before and after each flap was positioned around the heart. Stimulation was achieved by R-wave synchronous latissimus burst pacing at a ratio of 1:4, an amplitude of 5 V, a frequency of 33 Hz, and a duration of 30% of the R-R interval. Hemodynamic changes were again recorded during latissimus stimulation. Construction of the bilateral anterior wrap (static cardiomyoplasty) caused some depression of baseline hemodynamic function, which was greater than that caused by either the static right or

left anterior cardiomyoplasty. With stimulation of the muscles (dynamic cardiomyoplasty), the bilateral wrap caused significant biventricular augmentation. Evaluation of the components of the bilateral wrap demonstrated that dynamic right anterior cardiomyoplasty also provided significant biventricular augmentation, but the dynamic left anterior cardiomyoplasty augmented only right-sided variables. The mechanism of biventricular compression by the bilateral procedure is due mostly to the right wrap. The right anterior cardiomyoplasty may provide significant biventricular compression for treatment of heart failure, without the complexity associated with bilateral anterior cardiomyoplasty.

(*Ann Thorac Surg* 1993;55:72-7)

The shortcomings of current therapy for congestive heart failure have made it clear that new approaches to this problem are needed [1, 2]. Dynamic cardiomyoplasty is a procedure in which a pedicled latissimus dorsi muscle is wrapped around the heart and paced in synchrony with systole to improve the function of the failing heart. Traditionally, the left latissimus muscle has been employed for cardiomyoplasty because of its close proximity to the heart. Experimental reports have demonstrated that the left latissimus muscle can produce hemodynamic augmentation of an acutely failed left ventricle [3]. However, similar proof of hemodynamic improvement in an animal model of normal ventricular function has been elusive [4].

Bilateral cardiomyoplasty was conceived as a method for covering both ventricles with skeletal muscle to provide biventricular hemodynamic augmentation [5]. Experimental studies have shown significant augmentation of normal [6] and depressed [7] ventricular function with this form of cardiomyoplasty. This experiment was designed to analyze the mechanism of improved biventricular augmentation of a bilateral anterior cardiomyoplasty (BAC). The hemodynamics of BAC in an acute setting were compared with those of its component parts, the left

anterior cardiomyoplasty (LAC) and the right anterior cardiomyoplasty (RAC).

Material and Methods

Eight adult mongrel dogs weighing 27 to 31 kg underwent bilateral latissimus dorsi cardiomyoplasty in a two-stage procedure separated by 7 to 10 days. In the first stage, both latissimus dorsi muscles were mobilized from the chest wall to interrupt all sources of blood supply to the muscles except that from the thoracodorsal pedicles. A "vascular delay" period of 7 to 10 days was used before undertaking the next stage of the procedure, which allowed time for the muscles to recover from division of chest wall perforating vessels. A customized bifurcated paraneural bipolar stimulation lead (Fig 1) was secured to each proximal thoracodorsal nerve. The third end of the three-prong lead was attached to the pacing port of a Prometheus cardiomyostimulator (Medtronic, Inc, Minneapolis, MN).

During the second stage of the experiment, the origins of the latissimus dorsi muscles were separated from their fascial attachments. The humeral insertions of the latissimus dorsi muscles were left intact. Each muscle was then transposed into its respective thorax after resection of a 5- to 7-cm portion of the lateral second or third rib. The bilateral incisions were closed, and a median sternotomy was performed.

The animals were instrumented in the following fashion. A flow-directed pulmonary artery catheter and a

Fig 1. Prometheus cardiomyostimulator with attached screw-in sensing leads (left) and custom-made bifurcated paraneural stimulation leads (right).

Millar transducer-tipped aortic catheter were introduced from the femoral vessels. After the pericardium was opened, saline-filled plastic catheters were placed directly into the right ventricle, left ventricle, and left atrium and connected to pressure transducers. A 16-mm ultrasonic flowprobe (Transonic Systems, Inc, Ithaca, NY) was placed around the ascending aorta for measurement of aortic flow. All hemodynamic variables were recorded simultaneously by an IBM-AT computer through an analog to digital converter. The data were then analyzed using CODAS and ASYSTANT software (Dataq Instruments, Inc, Akron, OH).

Two epicardial unipolar sensing leads (model 4951, Medtronic) were placed on the anterior wall of the right ventricle. These were connected through a Y-adaptor (model 5866-24, Medtronic) to the sensing port of the Prometheus cardiomyostimulator (see Fig 1).

The BAC consists of two component parts: the RAC and the LAC (Fig 2). Each of these components was applied to the heart in an anterior cardiocostal fashion [8], that is, with the proximal portion of the muscle on the anterior heart and the deep (costal) surface abutting the epicardium. For the creation of an RAC (Fig 3), the lumbodorsal

origin of the right latissimus dorsi muscle was secured to the posterior pericardium at the level of the atrioventricular groove. The proximal muscle flap and its fibers lie on the anterior wall nearly parallel to the long axis of the heart. Construction of the LAC has been previously described [9]. In this type of cardiomyoplasty the fibers of the LAC are parallel to short axis of the heart (perpendicular to the intraventricular septum). The BAC created by placing an LAC on top of the RAC for an encircling "criss-cross" effect on the ventricles.

Baseline hemodynamic measurements were taken before the application of the three cardiomyoplasty wraps to the heart. Latissimus muscles were then retrieved from their respective chest cavities and BAC, LAC, and RAC wraps were performed in each dog in a random order. After each flap was positioned around the heart, a second set of hemodynamic variables was recorded with the muscles in an unstimulated, "static" state.

To prevent muscle fatigue, these nonconditioned latissimus muscles were then burst-paced in synchrony with systole at a ratio of 1 muscle contraction to every 4 heart beats. Cardiomyostimulator-programmed pacing parameters included an amplitude of 5 V, a burst frequency of 33 Hz, a pulse width of 210 microseconds, and a burst duration of 30% of the R-R interval. Hemodynamic measurements were then recorded during "dynamic" cardiomyostimulation.

All animals received humane care in compliance with the "Guide for the Care and Use of Laboratory Animals," published by the National Institute of Health (NIH publication No. 85-23, revised 1985). All animals were killed after completion of hemodynamic studies.

Results

Each dog served as its own control for statistical analyses. Intraflap hemodynamic analyses of dynamic cardiomyostimulation were done using paired *t* testing with significance interpreted as *p* less than 0.05. Interflap comparisons were performed by repeated-measures analysis of

Fig 2. The bilateral anterior cardiomyoplasty is composed of a right anterior and left anterior latissimus flap in a "criss-cross" configuration.

Fig 3. The right anterior cardiomyoplasty sling: (A) anterior view and (B) posterior view. Note the complete biventricular coverage obtained with this flap and parallel positioning of the latissimus fibers to the intraventricular septum throughout.

variance. Significance levels were set at p less than 0.02 with Bonferroni's correction applied.

Baseline Hemodynamics

Baseline hemodynamic variables recorded for each cardiomyoplasty showed no significant differences in right- or left-sided variables through the course of these experi-

ments (Table 1). This indicates that the hemodynamic stability of the native cardiovascular system was maintained over the course of the experiment.

Mean baseline values are shown on all further tables of intraflap comparisons for purposes of simplifying the illustrations. However, statistical comparisons with baseline function were continued in a paired fashion.

Table 1. Baseline Hemodynamics ($n = 8$)

Variable	Bilateral Cardiomyoplasty	Left Cardiomyoplasty	Right Cardiomyoplasty
RV (mm Hg)	32 ± 3	31 ± 2	31 ± 3
RV dP/dt (mm Hg/s)	452 ± 75	423 ± 70	435 ± 80
PA (mm Hg)	26 ± 3	26 ± 2	26 ± 3

LV dP/dt (mm Hg/s)	$2,086 \pm 169$	$1,996 \pm 119$	$1,966 \pm 200$
Ao P (mm Hg)	98 ± 5	100 ± 4	97 ± 5
Ao flow (L/min)	15.1 ± 1.0	14.7 ± 0.9	14.3 ± 1.1
RA (mm Hg)	7.3 ± 1.3	6.6 ± 1.1	7.4 ± 1.3
LA (mm Hg)	7.9 ± 1.5	8.0 ± 1.9	7.8 ± 1.5

Ao flow = peak aortic flow; Ao P = systolic aortic pressure; LA = left atrial mean pressure; LV = peak left ventricular pressure; LV dP/dt = rate of change of left ventricular pressure; PA = systolic pulmonary artery pressure; RA = right atrial mean pressure; RV = peak right ventricular pressure; RV dP/dt = rate of change of right ventricular pressure.

Table 2. Postwrap Hemodynamics ($n = 8$)

Variable	Baseline	Static Bilateral Cardiomyoplasty	Static Left Cardiomyoplasty	Static Right Cardiomyoplasty
RV (mm Hg)	31 ± 1	28 ± 1	27 ± 3	31 ± 1
RV dP/dt (mm Hg/s)	437 ± 41	206 ± 19 ^a	250 ± 27	235 ± 38
PA (mm Hg)	26 ± 1	23 ± 1	23 ± 2 ^a	27 ± 2
LV (mm Hg)	106 ± 4	78 ± 3 ^{a,b}	89 ± 2 ^a	91 ± 5 ^a
LV dP/dt (mm Hg/s)	2,016 ± 92	1,299 ± 93 ^{a,b}	1,660 ± 124 ^a	1,625 ± 138
Ao P (mm Hg)	98 ± 2	74 ± 3 ^{a,b}	86 ± 3 ^a	84 ± 3 ^a
Ao flow (L/min)	14.7 ± 0.6	8.9 ± 1.0 ^{a,b}	11.0 ± 0.9 ^a	10.3 ± 1.0 ^a
RA (mm Hg)	7.1 ± 0.7	9.3 ± 1.8 ^b	7.6 ± 1.3	9.6 ± 1.6 ^a
LA (mm Hg)	7.9 ± 0.9	9.4 ± 2.0	8.9 ± 1.6	9.3 ± 1.7

^a $p < 0.05$ versus baseline. ^b $p < 0.01$, bilateral cardiomyoplasty versus left cardiomyoplasty or right cardiomyoplasty.

Ao flow = peak aortic flow; Ao P = systolic aortic pressure; LA = left atrial mean pressure; LV = peak left ventricular pressure; LV dP/dt = rate of change of left ventricular pressure; PA = systolic pulmonary artery pressure; RA = right atrial mean pressure; RV = peak right ventricular pressure; RV dP/dt = rate of change of right ventricular pressure.

Static Postwrap Hemodynamics (Unstimulated)

The placement of unstimulated muscle mass around the heart (static cardiomyoplasty) caused some depression of the native baseline hemodynamic ventricular function (Table 2). The static BAC caused significant depression of right ventricular rate of pressure change (dP/dt), left ventricular peak pressure and dP/dt, aortic systolic pressure, and peak aortic flow. The unstimulated LAC effected a decrease in systolic pulmonary artery pressure, peak left ventricular pressure and dP/dt, aortic systolic pressure, and peak flow. Application of the static RAC to the heart depressed the least number of hemodynamic variables. Significant negative alterations were observed in peak left ventricular pressure, systolic aortic pressure, and aortic flow.

Analysis by repeated-measures analysis of variance showed that the static BAC caused more disturbance of normal hemodynamics than either of the unilateral wraps. The changes associated with static RAC or LAC were minor.

Dynamic Cardiomyostimulator Hemodynamics

Hemodynamic results of dynamic cardiomyoplasty in all three groups are shown Table 3.

BILATERAL ANTERIOR CARDIOMYOPLASTY. Stimulation of the BAC produced biventricular compression, which resulted in augmentation of both right- and left-sided variables. Highly significant ($p < 0.01$) increases were seen in peak right ventricular (+60%), left ventricular (+19%), pulmonary artery (+35%), and aortic pressures (+11%). Significant ($p < 0.05$) improvements in right ventricular dP/dt (+16%) and peak aortic flow (+10%) were also seen. The increase in left ventricular dP/dt (+10%) was not statistically significant.

LEFT ANTERIOR CARDIOMYOPLASTY. The stimulated LAC provided significant augmentation of right-sided variables only. Right ventricular pressure (+37%), right ventricular dP/dt (+60%), and pulmonary artery systolic pressures (+22%) were significantly ($p < 0.05$) improved with latis-

Table 3. Stimulated Hemodynamics ($n = 8$)

Variable	Bilateral Anterior Cardiomyoplasty		Left Anterior Cardiomyoplasty		Right Anterior Cardiomyoplasty	
	Static	Dynamic	Static	Dynamic	Static	Dynamic
RV (mm Hg)	28 ± 1	45 ± 3 ^a	27 ± 3	37 ± 3 ^b	31 ± 1	42 ± 3 ^a
RV dP/dt (mm Hg/s)	206 ± 19	549 ± 108 ^b	250 ± 27	401 ± 59 ^b	235 ± 38	492 ± 78 ^b

LV (mm Hg)	78 ± 3	93 ± 6 ^a	89 ± 2	91 ± 4	91 ± 5	102 ± 6 ^a
LV dP/dt (mm Hg/s)	1,299 ± 93	1,436 ± 156	1,660 ± 124	1,700 ± 176	1,625 ± 138	1,856 ± 193
Ao P (mm Hg)	74 ± 3	82 ± 5 ^a	86 ± 3	86 ± 3	84 ± 3	93 ± 4 ^a
Ao flow (L/min)	8.9 ± 1.0	9.8 ± 1 ^b	11.0 ± 0.9	11.1 ± 0.9	10.3 ± 1.0	11.7 ± 1.1 ^a
RA (mm Hg)	9.3 ± 1.8	11.1 ± 1.3	7.6 ± 1.3	8.0 ± 1.3	9.6 ± 1.6	10.0 ± 1.8
LA (mm Hg)	9.4 ± 2.0	9.9 ± 1.9	8.9 ± 1.6	8.9 ± 1.5	9.3 ± 1.7	9.9 ± 1.9

^a $p < 0.001$, static versus dynamic. ^b $p < 0.05$, static versus dynamic.

Ao flow = peak aortic pressure; Ao P = systolic aortic pressure; LA = left atrial mean pressure; LV = peak left ventricular pressure; LV dP/dt = rate of change of left ventricular pressure; PA = systolic pulmonary artery pressure; RA = right atrial mean pressure; RV = peak right ventricular pressure; RV dP/dt = rate of change of right ventricular pressure.

simus contraction. Although augmentation was seen, the increases in left-sided hemodynamic variables produced by the LAC alone were not great enough to be statistically significant.

RIGHT ANTERIOR CARDIOMYOPLASTY. Synchronized contractions of the RAC produced highly significant changes in both right- and left-sided hemodynamic measurements. Right ventricular pressure was increased 35% over the postwrap baseline ($p < 0.01$), right ventricular dP/dt improved 109% ($p < 0.05$), and systolic pulmonary artery pressures increased 26% ($P < 0.05$). Left ventricular pressure increased by 12% with stimulation, aortic pressure was up 13%, and aortic flow improved an average of 14% ($p < 0.01$ for all).

DATA SUMMARY. The dynamic BAC caused large increases in systolic pressure, but also was associated with significant depression in baseline function. The LAC minimally affected baseline function and caused minimal changes in cardiac hemodynamics with stimulation. The RAC, however, combined the best of both situations. The initial depression of function in the static state was minimal, whereas the augmentation of ventricular function in the dynamic state was significant. The dynamic effects of all of these wraps were not due to changes in systolic preload, as there were no significant differences in left atrial mean pressure with static or dynamic cardiomyoplasty.

Comment

Clinical review of patients with left latissimus cardiomyoplasty has shown that those patients with compromised biventricular function do not fare as well as those with isolated left ventricular failure. Impaired right ventricular ejection fraction has been found to be a predictor of poor outcome with clinical left latissimus cardiomyoplasty [10]. Previous canine experiments with right latissimus cardiomyoplasty applied to the right ventricle have shown improvements in right-sided variables [11, 12]. Bilateral ventricular support has been achieved with the use of a hybrid right latissimus cardiomyoplasty and a mechanical left ventricular assist device [13]. The concept of bilateral cardiomyoplasty was an effort to alleviate right ventricular function as a risk factor by providing biventricular compression of the heart.

Bilateral latissimus dorsi cardiomyoplasty was first hypothesized by Chachques and associates [5]. The procedure was subsequently developed simultaneously by Stephenson's group [8] and our own [7] using different pacing circuits. Significant improvements in global ventricular function were demonstrated by both groups. This study was undertaken to determine the mechanism by which the BAC produces changes in the hemodynamic function of both ventricles. This was done through an analysis of the component parts (LAC and RAC) of the BAC and a search for possible synergy between these two flaps.

Some initial depression of cardiac function occurred

with each type of cardiomyoplasty. However, the mechanism and duration of this disturbance was not investigated. It is our impression that this is a temporary situation caused by displacement of the very mobile canine heart from its normal position when the cardiomyoplasty is performed. However, additional research is needed to evaluate this further. The static BAC caused the largest initial disturbance, which made it easier to demonstrate improvements with stimulation. That is, the hemodynamic changes that occur for a given amount of force applied by contraction of the latissimus dorsi are greater for a depressed ventricle than a normal one. The static LAC and RAC caused minor changes in baseline function, but improvements were seen with dynamic stimulation.

We and others have previously published experimental data that show a left latissimus cardiomyoplasty can improve left ventricular function. The design of these earlier studies was different from the present one in that animals with severe acute heart failure were used. Hemodynamic changes were again more easily demonstrated on these depressed ventricles. The present study tested three types of cardiomyoplasty in each of several animals with normal cardiac function. Although the clinical application of cardiomyoplasty is for patients with heart failure, it would seem that hemodynamic augmentation in a nondepressed ventricular model would be a more stringent test of cardiomyoplasty function.

The synergy between the LAC and RAC that was hypothesized before this experiment was not found. The primary mechanism of biventricular compression produced by BAC is due mostly to the effects of the RAC. In fact, the dynamic RAC produced biventricular hemodynamic improvement not significantly different from that of the BAC. The LAC produced only minimal changes in left ventricular function, which were smaller than those seen with the RAC.

The combination of minimal initial hemodynamic disturbance and maximal biventricular augmentation makes the RAC an attractive procedure for clinical application. Neither the static nor the dynamic LAC caused any large changes in cardiac function. The initial disturbances caused by the static BAC might not be tolerated by a patient with heart failure, especially during the 6-week conditioning period required after the procedure. In addition, performance of a BAC would be a long and complex operation.

There are several possible explanations for the effects of the dynamic RAC. It has previously been shown that anterior positioning of the bulk of latissimus muscle provides improved dynamic augmentation [9]. Ventricular augmentation by the RAC is dependent on contraction of the well-vascularized proximal flap. The distal portion of the right latissimus muscle acts only as an anchor, which converts linear muscular contraction into ventricular compression. Alignment of muscular fibers parallel to the intraventricular septum provides better shortening in the anterosuperior diameter of the left ventricle, which may be important to cardiomyoplasty success [14]. The

RAC achieves both of these goals (see Fig 3). In addition, the fan-shaped spread of the right muscle allows complete biventricular coverage when applied in this slinglike fashion. Finally, contraction of the RAC pulls the ventricle in a direction nearly parallel to the net vector of blood flow through the aortic valve, which might be a more efficient method to assist the left ventricle.

The major limitation of this experiment is that it was an acute study that used animals with normal ventricular function and unconditioned latissimus dorsi muscles. As such, the results cannot be readily extrapolated to the clinical realm of failed ventricles with conditioned cardiomyoplasties. The study was performed in an acute fashion so that direct comparisons of each type of wrap could be made in the same animal. Chronic studies are now in progress to evaluate the hemodynamic effects of several types of cardiomyoplasty in animals with impaired ventricular function. There will likely be some loss in muscle strength with chronic stimulation, but studies from this laboratory show that the change is relatively small [15]. It is difficult to improve the function of a normal ventricle. The effects of cardiomyoplasty should be more readily demonstrated in the chronic state if the animals have some impairment of cardiac function.

In summary, these data show that the static BAC depresses cardiac function, but dynamic BAC results in biventricular augmentation. The LAC has minimal effects on baseline function but causes minimal changes in cardiac hemodynamics with stimulation. The RAC, however, combines the best of both situations. It minimally depresses the native hemodynamics of the ventricles in its static state while providing superior augmentation of ventricular function in its dynamic state. The RAC may be solely responsible for the hemodynamic effects seen with BAC. A single RAC can provide the benefits of the BAC without the complexity and initial hemodynamic disturbance associated with BAC.

Skeletal Muscle Ventricles: Left Ventricular Apex to Aorta Configuration

Huiping Lu, MD, Robert Fietsam, Jr, MD, Robert L. Hammond, BA, Hidehiro Nakajima, MD, Frank W. Mocek, MD, Gregory A. Thomas, MD, Renato Ruggiero, MD, Hisako Nakajima, MD, Michael Colson, MS, and Larry W. Stephenson, MD

Skeletal muscle ventricles (SMVs) were constructed from the latissimus dorsi muscle in 6 dogs. After 3 weeks of vascular delay followed by 6 weeks of 2-Hz continuous electrical conditioning, a valved conduit was placed between the left ventricular apex and the SMV and a second valved conduit, between the SMV and the aorta. The SMV was stimulated to contract during diastole at a 1:2 ratio with the heart. The SMV pumped 47% of the systemic blood flow initially (0.73 ± 0.23 versus 1.54 ± 0.42 L/min) and 40% after 3 hours. Skeletal muscle ventricle stimulation resulted in a 58% increase in mean

diastolic pressure initially (52 ± 9 to 82 ± 11 mm Hg; $p < 0.05$) and a 73% increase (45 ± 7 to 78 ± 8 mm Hg) after 3 hours of continuous pumping. This was associated with a 68% increase in the endocardial viability ratio initially and a 63% increase at 3 hours. The systolic tension-time index decreased by 26% initially and 25% at 3 hours. This study indicates that the SMV configuration of left ventricular apex to aorta may be particularly suitable for left ventricular assist.

(*Ann Thorac Surg* 1993;55:78–85)

Various skeletal muscles have been used in attempts to augment cardiac function. One method has been to wrap skeletal muscle directly around the failing heart and then stimulate the skeletal muscle to contract during cardiac systole [1–3]. This method, known as cardiomyoplasty, is currently undergoing phase II clinical trials in the United States. Skeletal muscle has been wrapped directly around the aorta and stimulated during diastole in an attempt to use the muscle as an aortic diastolic counterpulsator [4, 5]. Skeletal muscle pumps have also been coupled with the circulation either directly or indirectly using numerous other ingenious methods [6–17].

In our laboratory, pumping chambers of various shapes have been constructed from canine latissimus dorsi muscle [6–11, 13]. We refer to these blood pumps as skeletal muscle ventricles or SMVs. The purpose of this experiment was to evaluate the pumping characteristics of an SMV coupled between the left ventricular (LV) apex and the ascending aorta.

Material and Methods

Skeletal Muscle Ventricle Construction

Six adult mongrel dogs weighing 16 to 20 kg were operated on in accordance with the "Guide for the Care and Use of Laboratory Animals" published by the National

Institutes of Health (NIH Publication No. 85-23, revised 1985). Anesthesia was induced by intravenous administration of thiamylal sodium (15 mg/kg). The animals were then intubated and placed on a ventilator. Anesthesia was maintained with 2% isoflurane.

Through a left flank incision, the latissimus dorsi muscle was mobilized from the chest wall and surrounding tissues except for its neurovascular pedicle and tendinous insertion to the humerus. A bipolar cuff nerve electrode (Medtronic, Inc, Minneapolis, MN) was placed around the left thoracodorsal nerve for subsequent muscle stimulation. The latissimus muscle was then wrapped approximately 1.5 times around a cylindrical plastic mandrel (diameter, 3.4 cm; volume, 2.5 mL/kg dog weight). A Teflon felt (USCI, Billerica, MA) sewing ring 5 mm wide was used to secure the muscle edge to the base of the mandrel with 5-0 polypropylene. A few interrupted sutures of 4-0 chromic were placed to secure the muscle layers. A 6- to 7-cm portion of the second and third ribs was excised, and the SMV was placed in the apex of the thoracic cavity. The nerve electrode was connected to a neurostimulator (Itrel model 7421; Medtronic, Inc), which was placed through a separate incision under the left rectus abdominis muscle. The wounds were closed in layers.

After a 3-week vascular delay period, the stimulator was activated to deliver 2-Hz continuous stimulation of 210- μ s pulse duration and 1-V amplitude. Electrical stimulation was continued for 6 weeks to induce transformation of muscle fibers to a more fatigue-resistant state [18, 19].

Accepted for publication April 23, 1992.

Fig 1. Gore-Tex base cap was used between the skeletal muscle ventricle (SMV) and the valved conduit.

Connection of Skeletal Muscle Ventricle to Circulation

After the 3-week vascular delay and 6-week electrical conditioning periods, a second operation was performed. The animals were anesthetized as before. The heart was exposed through a median sternotomy, and the plastic mandrel was removed from the SMV. After the pericardium was incised, two myocardial leads (sutureless type 6917A-35T; Medtronic, Inc) were placed on the right ventricle for sensing. Two valved conduits were used to connect the SMV to the circulation. The conduits consisted of a woven Dacron tube with a porcine valve 14 mm in diameter (Hancock; Medtronic, Inc). The afferent conduit connected the LV apex to the SMV, and the efferent conduit connected the SMV to the ascending aorta. A circular piece of Gore-Tex material (W. L. Gore & Associates, Inc, Flagstaff, AZ) was used to cap the base of the SMV. Two circular openings 14 mm in diameter were made for inflow and outflow. Each conduit was sutured to an opening in the Gore-Tex base cap with continuous 6-0 polypropylene suture. The valves were placed 1.5 cm from the SMV base. The Gore-Tex base cap was then sutured to the SMV with 4-0 polypropylene suture (Figs 1, 2). Continuous suture of 6-0 polypropylene was used to anastomose the efferent conduit to the aorta.

The afferent conduit was anastomosed to the LV apex without cardiopulmonary bypass. A soft plastic connecting tube (inner diameter, ¼ inch [6.25 mm]; length, ⅝ inch [21.9 mm]; Cobe Laboratories, Inc, Lakewood, CO) was used to couple the LV apex to the afferent conduit. A double pursestring suture of 4-0 braided polyester was placed in the ventricular apex, through which a 1.2-cm incision was made with a No. 10 blade, and the connector was inserted (see Fig 2). A dose of 1,000 units of heparin sodium and 1 mL of 2% lidocaine hydrochloride were administered intravenously before this maneuver. All air was aspirated from the SMV and the conduits, and they then were filled with a solution of 0.9% sodium chloride.

Skeletal Muscle Ventricle Stimulation Protocol

After the SMV was connected to the circulation, a rate-responsive synchronized pulse train stimulator (Prom-

theus; Medtronic, Inc) was connected to the nerve lead and heart-sensing leads. The pacemaker was programmed to deliver a 33-Hz burst of electrical stimulation with a delay of 30% to 35% of the R-R interval to provide diastolic counterpulsation, a burst duration of 30% of the R-R interval, a 2- to 3-V amplitude, and a 1:2 (SMV to heart) contraction ratio.

Measurements

After the SMV was activated to pump blood continuously, SMV function and hemodynamic measurements were assessed hourly for 3 hours. The last dog was followed up for 10 hours. At each hour, measurements were made first with the stimulator on. The stimulator was then turned off, and after 3 minutes of equilibration, measurements were obtained with the stimulator off. The stimulator was then switched on again. The femoral and carotid artery pressures were recorded with a fluid-filled manometer line connected to a transducer. Left ventricular pressure and SMV pressure were measured directly with a 5F microtransducer-tipped catheter (Millar Instruments Inc, Houston, TX). Cardiac output was recorded using a 16-mm ultrasonic flow probe (Transonic Systems Inc, Ithaca, NY) placed around the main pulmonary artery. Flow generated by the SMV was recorded with a 16-mm flow probe positioned around the efferent conduit. Data were collected with a Gould ES 1000B recording and display system. After these acute experiments, all the animals were killed with intravenous KCl while they were under isoﬂurane anesthesia.

Calculation

Cardiac output and SMV output were calculated by integrating the respective flow curves using a digitizing pad

Fig 2. Skeletal muscle ventricle (SMV) connected between the left ventricular (LV) apex and the ascending aorta (intrathoracic position).

EQUATIONS

$$TTI = \overline{BP}_{sys} \times t_s = \text{shaded area}$$

$$EVR = \frac{(\overline{BP}_{dia} - LVedp) \times t_d}{TTI} = \frac{\text{shaded area}}{\text{shaded area}}$$

Fig 3. Calculation of tension-time index (TTI) and endocardial viability ratio (EVR). ($\overline{BP}_{dia}$ = mean diastolic blood pressure; BP_{sys} = systolic blood pressure; $\overline{BP}_{sys}$ = mean systolic blood pressure; $LVedp$ = left ventricular end-diastolic pressure; t_d = diastolic time interval; t_s = systolic time interval.)

(Digi-Pad 5; GTCO Corp, Rockville, MD) linked to a portable computer (T-3200; Toshiba, Irvine, CA). Mean pressure was calculated as the pressure area divided by time. The endocardial viability ratio [20] and systolic pressure tension-time index [21] were calculated from pressure curves as analyzed with the digitizing pad and portable computer (Fig 3). The stroke work was calculated as the product of the stroke volume and mean arterial pressure. Comparison of the mean diastolic arterial blood pressure with the stimulator off versus on was used to assess SMV diastolic augmentation.

For the purpose of presenting data, the "presumed" LV output (with the SMV on) was calculated as SMV flow subtracted from pulmonary artery flow. This represents the blood flow expected to cross the aortic valve and does not take into account the blood that enters the left ventricle and flows passively or that is pumped into the SMV.

Data are expressed as the mean $\pm$ the standard deviation. Statistical analysis was performed by paired *t* test using RS/1 software (copyright 1986, Bolt Beranek and Newman Inc, Cambridge, MA).

Results

The SMV contraction rate, the peak pressure generated by the SMV, and the end-diastolic pressure remained relatively constant over 3 hours (Table 1). The SMV stroke volume, which was 92% of the cardiac stroke volume initially (13.2 ± 5.4 versus 14.3 ± 4.6 mL), increased 10% at 1 hour (14.5 ± 4.6 mL) and then decreased to 80% of its initial volume after 3 hours (10.6 ± 3.5 mL). As the SMV contraction rate was half of the native heart rate, the SMV output was initially 47% of the systemic blood flow (pulmonary artery flow) (0.73 ± 0.23 versus 1.54 ± 0.42 L/min) and 40% of the systemic blood flow at 3 hours (0.60 ± 0.15 versus 1.52 ± 0.62 L/min). These changes are represented in Figure 4A. Initially, the SMV stroke work was 91% of that of the left ventricle ($0.92 \pm 0.35 \times 10^6$ versus $1.01 \pm 0.39 \times 10^6$ ergs). After 3 hours of continuous pumping, the SMV stroke work was 72% of its initial value ($0.66 \pm 0.14 \times 10^6$ ergs).

The hemodynamic variables measured initially and at each hour with the SMV stimulator off and on are recorded in Table 2. At the beginning, SMV stimulation resulted in a 58% increase in mean diastolic arterial blood pressure (52 ± 9 to 82 ± 11 mm Hg; $p < 0.05$). Over the next 3 hours, the augmentation with SMV stimulation increased to 62%, 66%, and 73.3% (Fig 4B). Because the calculation of the endocardial viability ratio is dependent on the average pressure during diastole, the mean diastolic arterial blood pressure augmentation was associated with a 68% increase in this ratio initially (1.12 ± 0.08 versus 1.88 ± 0.15 ; $p < 0.05$) and 66%, 62%, and 63% increases at 1 hour, 2 hours, and 3 hours, respectively (Fig 4C).

Throughout the 3-hour experiment, there was an average 6% increase in both the mean arterial blood pressure and the systemic blood flow with the SMV stimulator on

Table 1. Function of Skeletal Muscle Ventricle

Variable	Start	1 Hour	2 Hours	3 Hours
SMV contractions (no./min)	55 ± 7	55 ± 6	55 ± 6	54 ± 5
SMV peak systolic pressure (mm Hg)	91 ± 10	91 ± 9	84 ± 16	88 ± 7
SMV end-diastolic pressure (mm Hg)	8 ± 3	8 ± 4	9 ± 5	9 ± 4
SMV stroke volume (mL)	13.2 ± 5.4	14.5 ± 4.6	11.7 ± 6.9	10.6 ± 3.5
SMV stroke work (10^6 ergs)	0.92 ± 0.35	0.86 ± 0.35	0.74 ± 0.32	0.66 ± 0.14
SMV output (L/min)	0.73 ± 0.23	0.71 ± 0.35	0.63 ± 0.33	0.60 ± 0.15

SMV = skeletal muscle ventricle.

Fig 4. (A) Stroke volume, stroke work, and output of skeletal muscle ventricle (SMV) compared with native heart control (SMV off). (B) Diastolic arterial pressure change with SMV contraction off and on. (C) Increases in endocardial viability ratio with SMV contraction on. (D) Decreases in systolic tension-time index with SMV contraction on.

versus off. In contrast, the systolic arterial blood pressure was consistently decreased during the 3 hours with the SMV stimulator on versus off. Consequently, the mean arterial blood pressure during systole was decreased. The systolic tension-time index was decreased, initially by 26% (16.9 ± 2.7 versus 12.5 ± 3.3 mm Hg · s; $p < 0.05$) and after 3 hours, by 25% (Fig 4D).

The single animal studied over 10 hours had similar decreases in stroke volume, SMV output, and stroke work during the initial 3 to 4 hours. However by 7 hours, there was an increase in these variables that exceeded their original values (Fig 5). This change was achieved by a decreased systolic arterial pressure (92 ± 11 versus 82 ± 10 mm Hg; $p < 0.05$). The SMV pressures remained

constant from 3 hours to 10 hours. Representative hemodynamic recordings at 3 hours and 10 hours are seen in Figure 6.

Comment

Skeletal muscle ventricles of different shapes have been tested in our laboratory acutely and chronically. These muscle pumps have been evaluated in mock circulation circuits and as assist devices for both the pulmonary and systemic circulations [6-11, 13, 22]. The SMV configuration with valved conduits coupled between the left ventricle and the aorta presented herein has not previously been evaluated by our group. Although this was an acute

in-circulation experiment, the hemodynamic results are the best we have obtained in that 40% to 47% of the systemic blood flow was supplied by the SMV.

Where SMVs have been used as aortic diastolic counterpulsators, the aortic blood flow has usually been routed directly through the SMV [6-9, 16, 22]. We have connected the SMVs to the ascending aorta, but more commonly to the descending aorta, for diastolic counterpulsation. The stroke volume pumped by these SMVs has been in the range of 4 to 9 mL. The percent of LV blood pumped by these SMVs has been in the range of 17% to 20% [22, 23]. Canine SMVs do not seem to tolerate pumping rates of more than 100 contractions per minute for prolonged periods. Therefore, they are generally stim-

Fig 6. Hemodynamic recordings for the last dog at (A) 3 hours and (B) 10 hours with skeletal muscle ventricle (SMV) contraction off and on. (EKG = electrocardiogram; * = SMV stroke volume; ↑ = diastolic arterial pressure augmentation; and ↓ = left ventricular [LV] systolic pressure decrease; ↙ = LV tension-time decrease.)

ulated at a 1:2 ratio with the heart. For this reason, even when the stroke volume of the SMV is equal to that of the left ventricle, the power output is less.

These SMVs have functioned effectively as aortic counterpulsators for several months without evidence of thromboembolism. In 1 animal, an SMV pumped blood effectively for 27½ months [24]. Because skeletal muscle is less compliant than cardiac muscle, using the SMV as an aortic diastolic counterpulsator has the advantage that the SMV is supplied with a high filling pressure. These SMVs contract during diastole and relax during systole; therefore, the lowest pressure in the SMV cavity tends to range between 70 and 80 mm Hg. It is possible that constant pressures of this magnitude may be too high and hamper blood flow within the muscle layers of the SMV or cause other damage to the muscle over time.

We [10] have also evaluated SMVs pumping blood from

the left atrium to the aorta. This configuration requires two valves: one between the left atrium and the SMV and one between the SMV and the aorta. The SMV in this configuration also contracts during cardiac diastole, because if it pumped during cardiac systole, it would be pumping against LV ejection. In animals with normal hearts, the left atrial pressures have remained in the range of 14 to 16 mm Hg over 3-hour experiments. The percentage of the systemic blood flow pumped by the SMV has been in the range of 21% to 27% of the cardiac output with SMVs pumping at a ratio of 1:2 with the heart. To date, we have not been successful in converting the left atrium to aorta SMV configuration into a chronic model. Higher filling pressures may be required over longer periods. It is possible that with a stable LV failure model, where filling pressures are higher, this configuration would function effectively for prolonged periods.

There are both experimental and clinical reports [25-27] in which blood has been routed, without an auxiliary pump, from the LV apex to the aorta with a valved conduit. Clinically, this valved-conduit technique has been used for the treatment of hypertrophic obstructive cardiomyopathies and idiopathic hypertrophic subaortic stenosis.

A variety of mechanical pumps have also been used to route blood flow from the LV apex to the aorta to bridge patients awaiting heart transplantation and to treat patients for other conditions causing profound LV failure [28].

Using an SMV to pump blood between the left ventricle and the aorta, as was done in this experiment, might overcome some of the potential problems encountered with other SMV configurations. As the SMV with the left ventricle to aorta configuration predominantly fills during LV systole, the potential problem of inadequate filling pressures with the left atrium to aorta configuration is overcome. In addition, because the pressure in the SMV cavity is equal to the LV end-diastolic pressure during a portion of the SMV pumping cycle, there is likely to be improved blood flow in the muscle layers of the SMV compared with the aortic diastolic counterpulsator configuration [23, 29, 30]. Other potential problems of continuous high pressure in the aorta to aorta configuration might also be avoided.

In other recent experiments [9], comparison was made between placing the SMV inside the thoracic cavity and placing it in the more conventional position on the chest wall. The intrathoracic SMVs were found to be more compliant and generated greater stroke work than those placed on the chest wall. The SMVs in the present study therefore were placed inside the thoracic cavity.

The Gore-Tex base cap used in this model also may have contributed to its success. Because the openings for the afferent and efferent conduits were properly sized, SMV inlet and outlet obstruction was likely avoided. Such obstruction could have occurred earlier when the base cap was not used.

During this 3-hour experiment, the systolic tension-time index was significantly lower with the SMV on versus off, which indicates that the myocardial oxygen requirement was reduced [21]. The endocardial viability ratio was significantly increased with the SMV on versus off, which indicates that the subendocardial blood flow was improved during SMV pumping [20].

Earlier, Brister and colleagues [31] and Stevens and co-workers [16] used unconditioned rectus muscle to pump blood between the left ventricle and the aorta. Muscle was wrapped around a bladder with a single valve. The model used by Brister's group had an afferent valve and that of Stevens's group, a valve in the efferent limb of the conduit. Brister and associates apparently did not measure flow but did observe augmentation of diastolic aortic pressures. In the acute heart failure model of Stevens and colleagues, cardiac output was initially increased 31% over control while the muscle pump was functioning, but only 8% over control at 1 hour. In the current experiment, cardiac output increased only slightly

with the SMV functioning. This may have been because our animals had normal hearts, whereas the animals in the study by Stevens and co-workers were in heart failure.

Although cardiac output in the current experiment improved only slightly with the SMV pumping, 47% of the systemic blood flow was pumped by the SMV rather than the left ventricle. Although the percentage of blood pumped by the SMV compared with that pumped by the left ventricle did decrease over the 3-hour study (47% initially to 40% at 3 hours), the deterioration in function was not nearly as rapid as in the study by Stevens's group [16]. This may have been because they used unconditioned muscle, whereas the muscle in our study had been electrically conditioned to make it more fatigue-resistant. Electrical conditioning of a muscle also causes the muscle to lose some strength. This could explain why the initial increase in cardiac output seen in the study by Stevens and associates was greater than that seen in our study. The fact that Stevens and associates used a different muscle, ie, rectus versus latissimus, also may have contributed to this difference.

In the animal followed up for 10 hours, SMV function stabilized after 3 to 4 hours. From previous experience, this stabilization in function over several hours indicates that about the same level of SMV performance is likely to occur in a chronic setting [32].

Voytik and co-workers [33] used electronics to model the human circulation as resistive-capacitive networks, with pressures as voltages, blood flow as electrical current, cardiac valves as diodes, heart chambers and great vessels as capacitors, and capillary beds as resistors. Their data from the models of different SMV configurations demonstrated the superiority of the LV apex to aorta design compared with an aorta to aorta or atrium to aorta design. The LV apex to aorta model provided greater augmentation of the total cardiac output, greater reduction of the mean LV power, and greater mean SMV power in both the normal heart and a heart failure simulation.

There are several limitations to the current study. Two valves were used in this model, which makes it a more efficient pump system but gives it the potential for more complications long term. This was a short-term study, and it is not yet known whether the same level of SMV performance can be sustained in long-term studies. In this study the animals had normal hearts, and it is not known how well this SMV system would perform during heart failure, which in fact, would be more clinically relevant. However, it is encouraging that in the experiments by Stevens and colleagues [16] discussed earlier, the animals were in heart failure, and systemic blood flow increased by 31% as opposed to 6% in our study.

Also, the true unloading effect that the SMV has on LV function is not completely clear at this point. We measured pulmonary flow and SMV blood flow as well as aortic, LV, and SMV pressure. By subtracting SMV flow from pulmonary artery flow, "presumed" LV output, the amount of blood in liters per minute that we assumed crossed the aortic valve, was obtained. We do not know that the same amount of blood that flowed across the pulmonary artery should have gone into the left ventricle

and then would have either been pumped into the aorta or been pumped or flowed passively into the SMV. It is unclear how much work was required by the left ventricle to fill the SMV. We do know that very little blood was ejected by the left ventricle during systole through the SMV into the aorta when the SMV was either off or on, as witnessed by the SMV flow traces in Figure 6.

In conclusion, this study demonstrates that the SMV configuration of LV apex to aorta with two valved conduits may be particularly suitable for LV assist. The SMV decreases LV work and oxygen consumption while increasing myocardial blood flow. This benefit was achieved by (1) SMV diastolic augmentation, (2) presystolic LV unloading into the SMV, and (3) valves that reduced regurgitant flow. More importantly, although systemic blood flow increased only slightly during SMV contraction, almost half of the systemic blood flow was pumped by the SMV rather than the left ventricle.

Prophylactic Digitalization Fails to Control Dysrhythmia in Thoracic Esophageal Operations

Andrew J. Ritchie, FRCSEd, Michael Tolan, FRCSI, Michael Whiteside, FRCSI, James A. McGuigan, FRCS, and John R. P. Gibbons, FRCS

Northern Ireland Regional Thoracic Surgical Department, Royal Victoria Hospital, Belfast, Northern Ireland, United Kingdom

A prospective, controlled, randomized study of 80 patients undergoing esophageal operations was undertaken, in which one group of patients was given digoxin and the other was not. The incidence of cardiac dysrhythmia was compared in each group. Twenty-six patients underwent operation for benign disease. Equal numbers were digitalized or not and no dysrhythmias occurred.

Fifty-four patients underwent operation for malignant disease. Of 26 in the group digitalized, 12 suffered dysrhythmia (46%). Of 28 not digitalized, 9 suffered dysrhythmia (32%). Overall, 39% of patients with malignant disease suffered a dysrhythmia compared with none with benign disease ($p < 0.002$ by χ^2).

(*Ann Thorac Surg* 1993;55:86-8)

The role of thoracic surgery in the treatment of benign and malignant disease of the esophagus has been established since the work of Heller [1] and Torek [2]. Digitalis was discovered and first used successfully by William Withering of Birmingham more than 200 years ago. It was first used in the treatment of heart failure associated with atrial fibrillation in 1911 [3]. A specific and significant association of atrial fibrillation with thoracic surgical procedures [4-6] led to the suggestion that digitalis was indicated as a prophylactic measure [7] to prevent this complication. This became established for both pulmonary and esophageal thoracic operations, although the etiology of the arrhythmias remains unclear [8]. There have been contradictory reports on the effectiveness of prophylactic digoxin [9-11], although none specific to esophageal thoracic operations. The role of digitalis has come under review with awareness of the potential of the drug itself to induce arrhythmia and the availability of safer alternatives [12]. This led us to reevaluate the role of prophylactic digoxin in esophageal thoracic operations for both benign and malignant disease.

Patients and Methods

Eighty consecutive patients who underwent elective thoracic esophageal operations were studied in an open, randomized clinical trial. Preoperative assessment included pulmonary function tests, electrocardiography, and measurement of urea and electrolyte levels and arterial blood gas tensions to determine suitability for operation. Patients with inadequate respiratory reserve, hypoxemia when breathing room air, or electrocardiographic evidence of myocardial infarction or a current

dysrhythmia and patients who were being treated for dysrhythmia were excluded from the study. Ten patients with documented myocardial disease entered the study. Those with malignant disease were well matched for age, sex, site of tumor, and operative intervention.

Patients were randomly allocated to preoperative digoxin (D) or no treatment (ND). A standard regimen of 500 μg at 18.00 hours and 22.00 hours the day before operation, followed by 250 μg with premedication, was given. Postoperatively, 250 μg digoxin was given daily for 9 days and adjusted according to serum levels (radioimmunoassay, Amerlex kit, Amersham, England; reference range, 1 to 2 $\mu\text{g/L}$).

Serum digoxin levels were measured immediately preoperatively and 6 hours after the oral dose on days 1, 3, 5, and 7 postoperatively. One of us participated in each procedure specifically to record details and assess patients. Constant screen monitoring of the electrocardiogram was chosen in preference to Holter monitoring to allow analysis of factors such as hypoxemia and hypokalemia to be assessed at the onset of a dysrhythmia. This commenced at the time of anesthetic induction and continued for at least 4 days, after which 12-lead electrocardiography was performed on alternate days. In the operative and recovery periods this was recorded by us. Patients were monitored by staff visually from the electrocardiographic trace, which had a preset dysrhythmia alarm after their return to the ward. Tracings were recorded automatically when a dysrhythmia occurred and analyzed by us, and subsequently by a cardiologist. Serum potassium and arterial blood gas tensions were determined at the time of onset of a dysrhythmia and treated as appropriate.

A dysrhythmia was defined as the first electrocardiographic rhythm abnormality recorded that persisted across one full monitor screen. Subsequent episodes of dysrhythmia in the same patient, and that group with

serum digoxin levels greater than 2 $\mu\text{g/L}$ who had bigemini, multifocal ventricular ectopics or T wave changes, were excluded from analysis. Statistical analysis was by χ^2 using Yates' correction where appropriate.

Results

Overall mortality was 6.25%. Five patients died within 30 days of operation: 2 had esophageal carcinoma resected by left thoracotomy and died postoperatively as a consequence of anastomotic breakdown, with two further deaths as a result of respiratory failure; one patient underwent left thoracotomy and repair of hiatus hernia by the Belsey Mark IV procedure and died 7 days postoperatively as a consequence of aspiration bronchopneumonia. The average age of those who died was not significantly different from their group as a whole, being 55 years for patients with benign disease and 69 years for patients with malignant disease. Of those given digoxin, 3 patients (4%) had serum digoxin levels below the therapeutic range immediately preoperatively.

Overall, 21 patients suffered cardiac dysrhythmia (26%) but none with benign disease. Fifty-four patients underwent operation for malignant disease. Of 26 in group D, 12 suffered dysrhythmia (46%) compared with 9 of 28 in group ND (32%). In the malignant disease group, 39% of patients suffered cardiac dysrhythmia compared with none with benign disease ($p < 0.002$ by the χ^2) (Table 1).

All the dysrhythmias that occurred would be expected to be prevented by or related to digoxin therapy. The average age of patients with malignant disease in group D was 66 years and in group ND, 74 years ($p < 0.02$). That there were no dysrhythmias in those patients undergoing thoracotomy for benign disease suggests that thoracotomy alone does not induce this complication. There was no difference in the incidence of dysrhythmia for each operative procedure. Some 76% of patients who had dysrhythmias at any time during follow-up had their initial dysrhythmic episode before the sixth postsurgical hour (Table 2). Of the patients who suffered dysrhythmia, all in group D required active intervention whereas those in group ND did not. In no case could the onset of dysrhythmia be related to hypoxia or serum potassium levels.

Comment

This randomized study reports the incidence of cardiac dysrhythmia in patients undergoing elective thoracic

esophageal operations for benign and malignant disease. Previous reports of such patients have been included in those undergoing thoracic operation mainly for pulmonary disease, but the interpretation of these reports is complicated by their retrospective nature and the variability of methods and groups under study [5, 13]. This study has confirmed cardiac dysrhythmia as a significant complication only for that group with malignant disease and suggests no benefit from prophylactic digitalization. All those in group D required intervention to treat their complication, whereas those in group ND did not.

These findings suggest a negative impact of digoxin because 46% of patients in group D, compared with 32% in group ND, with malignant disease suffered dysrhythmias. Although not a statistically significant difference ($p = 0.29$), this negative impact is substantiated by the requirement for intervention once dysrhythmia occurs. In group D, 7 patients suffered atrial fibrillation with uncontrolled ventricular rate resulting in lowering of mean arterial blood pressures. Three patients had persistent supraventricular tachycardia resulting in lowering of mean perfusion pressures. The other 2 patients had a combination of reentry arrhythmias resulting in multiple atrial and ventricular ectopics. The 9 patients in group ND who suffered dysrhythmia did not require intervention. Atrial fibrillation occurred in 6 patients without hemodynamic effect. One patient had supraventricular tachycardia controlled by carotid massage, and the other 2 patients had supraventricular paroxysmal tachycardia without hemodynamic effect. Seven (58%) of the 12 who required intervention suffered dysrhythmias before the sixth postoperative hour.

We believe the methods used in this study have allowed us to detect high incidence of cardiac dysrhythmia in 39% of those with malignant disease and to identify the operative and first 6-hour postoperative period as the most common time of onset. By identifying this period we can adjust our efforts to detect and control this complication. Several factors have been identified in the etiology of cardiac dysrhythmias in patients undergoing thoracic operations but none specific to esophageal operations [6, 12, 13]. In patients with benign disease only 1 case of dysrhythmia has previously been reported [14], indicating that thoracotomy per se does not induce this complication. There is a significant difference in age between those with benign and those with malignant disease ($p < 0.05$), which may partly explain this difference.

Increased vagal tone, hypoxia, and direct invasion by tumor have been thought to be important in those patients undergoing pulmonary operations [1, 6]. In this study the onset of dysrhythmia could not be related to

Table 2. Onset of Dysrhythmia in Malignant Disease

Dysrhythmia	Number	Percentage
Total dysrhythmias	21	39
Intraoperative	11	52
Up to 6 hours postoperative	5	24

hypoxia, operative manipulation, or specifically to site of tumor. In addition, there was no clear correlation in relation to length of operation or magnitude of dissection in each individual. In those patients suffering dysrhythmia, tumor was identified in the carinal nodes in 4 patients (7%). This, and the demonstration that the majority of cardiac dysrhythmias occur on the day of operation, indicate that other factors may be more significant in thoracic esophageal operations. All anesthetic agents currently used are potentially dysrhythmogenic. Limitation in the efficacy of digoxin, particularly in the older age group, has been suggested [12], emphasizing the dangers of dysrhythmogenicity [15] and toxicity [11]. None of our patients was hypokalemic or in renal failure at onset of dysrhythmia.

In conclusion, this prospective, randomized study in thoracic esophageal surgery has failed to demonstrate benefit from prophylactic digitalization, which is associated with an increased hazard in terms of incidence of cardiac dysrhythmia and its treatment. In addition, we have demonstrated that this complication is confined to patients with malignant disease and is more likely to occur on the day of operation in a generally older age group. Further efforts to identify the factors involved in extended prospective studies by ourselves and others may lead to a useful revision of the role of prophylactic digitalization and examine in detail these initial findings.

We are indebted to Mr J. Cosgrove, Dr D. Coppel, Dr N. Campbell, and Mr C. F. Harvey; and to Mr C. Patterson for statistical advice. The manuscript was typed by Miss M. Weller.

Benefits of Posttransplantation Monitoring of Interleukin 6 in Lung Transplantation

Yuichi Yoshida, MD, Yuichi Iwaki, MD, PhD, Si Pham, MD, James H. Dauber, MD, Samuel A. Yousem, MD, Adriana Zeevi, PhD, Shigeki Morita, MD, and Bartley P. Griffith, MD

Departments of Pathology and Surgery, University of Pittsburgh School of Medicine, Pittsburgh, Pennsylvania

To determine the predictive diagnostic value of interleukin 6 (IL-6) monitoring in lung and heart-lung transplants, we measured posttransplantation serum IL-6 levels in 17 adult lung or heart-lung transplant recipients. Posttransplantation IL-6 elevation patterns were classified into 4 groups: serum IL-6 level remained negative throughout the monitoring period (group 1; $n = 1$; 6%); several sharp spikes with normal baseline (group 2; $n = 9$; 53%); persistently high level of serum IL-6 (group 3; $n = 3$; 18%); and several sharp spikes of serum IL-6 elevation with abnormally high baseline (group 4; $n = 4$; 24%). One patient without an elevation of IL-6 (group 1) did not experience any episodes of rejection or infection. Nine patients in group 2 had 19 IL-6 spikes, 13 of which

were associated with histopathologically or clinically diagnosed rejection, 3 with acute bronchitis, and 1 with diffuse alveolar damage. Three patients in group 3 had persistent infections including cytomegalovirus infection, toxic megacolon, and repeated bacterial infection during the monitoring period, and 4 in group 4 died within 3 months after transplantation. From this study it appears that a spiked elevation of IL-6 could have a predictive value in diagnosing rejection, and persistently high levels of IL-6 indicate the presence of infection. Thus, IL-6 monitoring is beneficial for lung transplant recipients.

(*Ann Thorac Surg* 1993;55:89-93)

As lung transplantation becomes a more common therapeutic modality for patients with end-stage lung disease, the demand for timely diagnosis of infection and rejection increases proportionately. Presently, comprehensive diagnoses of rejection episodes in lung transplant patients are based on symptoms that include fever, chest roentgenographic changes, and worsening gas exchanges [1-3]. Histopathological diagnoses from transbronchial biopsies provide distinct information [4], although frequent biopsies are undesirable. Lymphocyte proliferative activity of bronchoalveolar lavage also provides supportive diagnostic evidence of rejection [5, 6] in lung transplant patients. However, in contrast to kidney or liver transplants, there are no adequate plasma or serum parameters to indicate rejection in lung transplant recipients.

Cytokines play a crucial role in mediating biological responses, particularly in self-defense systems. Interleukin 6 (IL-6), a pleiotropic cytokine, is released primarily by activated macrophages in addition to activated T lymphocytes followed by antigen presentation [7, 8]. In our previous study, IL-6 seemed to reflect the magnitude of a recipient's immune responses after lung transplantation [9].

Thus, we meticulously monitored serum IL-6 levels in lung transplant recipients to study whether or not an

elevation of serum IL-6 could provide any predictive value in diagnosing posttransplantation infection or rejection episodes.

Material and Methods

Patients

Subjects of this study, performed at Presbyterian University Hospital, University of Pittsburgh, between November 1990 and May 1991, were 17 adults aged 26 to 56 years (mean age, 38.9 years) who received either single-lung (6 patients), double-lung (9 patients), or heart-lung transplants (2 patients). The demographics of patient diagnoses are shown in Table 1. All grafts were harvested in a similar fashion and stored in Euro-Collins solution, and all patients received similar perioperative intensive care, as described earlier [1].

Immunosuppression

All patients received cyclosporine A with dosage adjusted to maintain blood levels at between approximately 700 ng/mL and 1,000 ng/mL (whole blood radioimmunoassay; Sandoz Pharmaceuticals, East Hanover, NJ). Methylprednisolone was administered three times (125 mg each) during first day after transplantation. Steroids were withheld during the first 2 postoperative weeks, after which prednisone administration was instituted at a maintenance dose of 20 mg/day. During this period, patients received a 3- to 5-day course of rabbit antithymocyte globulin. Azathioprine (2 to $3 \text{ mg} \cdot \text{kg}^{-1} \cdot \text{day}^{-1}$) was

Accepted for publication April 21, 1992.

Table 1. Demographics of 17 Lung Transplant Patients

Disease	N	Mean Age (y)	Sex M:F	Transplant		
				Single-Lung	Double-Lung	Heart-Lung
Primary pulmonary hypertension	2	38.5	1:1	0	2	0
Secondary pulmonary hypertension	5	33.4	1:4	1	2	2
Emphysema (α_1 -antitrypsin deficiency)	5 (3)	48.4	5:0	5	0	0
Lung fibrosis (cystic fibrosis)	5 (4)	34.4	5:0	0	5	0
Total	17	38.8	12:5	6	9	2

adjusted to maintain an absolute number of blood neutrophils greater than $2 \times 10^9/L$ ($2,000/\mu L$).

Diagnosis of Rejection

Biopsies were performed routinely at 2 and 4 weeks after transplantation and additionally when clinically indicated. This histopathological diagnosis of rejection was determined by transbronchial biopsy and made according to the working formulation for classifying and grading pulmonary rejection [4]. Briefly, acute cellular rejection was classified into four grades: grade 1, minimal acute rejection; grade 2, mild acute rejection; grade 3, moderate acute rejection; and grade 4, severe acute rejection. Indications for a clinical diagnosis rejection were a change in chest roentgenogram or clinical symptoms such as fever, increased coughing, worsening gas exchange, or a complaint of shortness of breath. Rejection episodes were treated initially with a steroid bolus.

Interleukin 6 Testing

Blood samples were collected daily for 2 to 4 weeks in glass tubes without anticoagulant agents. Serum was obtained immediately after centrifugation at 2,000 rpm for 10 minutes. Aliquots were stored in polypropylene tubes at $-70^\circ C$ until assayed.

Testing for IL-6 was performed by the two-step sandwich enzyme immunoassay method using an ELISA kit (Quantikine Human IL-6; R & D Systems, Inc, Minneapolis, MN). Briefly, 50 μL of assay buffer (buffered protein base) was added to 96-well microplates coated with mouse anti-human IL-6 monoclonal antibodies (first antibody), then 200 μL of serum was aliquoted to microplates. After a 2-hour incubation period at room temperature, the wells were washed and 200 μL of horseradish peroxidase-conjugated goat anti-human IL-6 polyclonal antibody was added. After an additional 2-hour incubation at room temperature, the wells were washed again and incubated at room temperature for 20 minutes with chromogen, a mixture of H_2O_2 and tetra-methylbenzidine. Then 50 μL of 2 N H_2SO_4 was added to stop the reaction, optical density at 450 nm was measured using a microtiter reader (Titertek Multiskan; Flow Laboratories, Inc, McLean, VA), and serum cytokine levels were obtained from the standard curve. Assay sensitivity was 10 pg/mL. More than 70

pg/mL of serum IL-6 was considered abnormal. A spike was considered as an elevation of more than 70 pg/mL from the normal value, which then became normal within 4 days.

Statistics

Statistical analysis was performed by the Welch *t* test. The difference was considered statistically significant when *p* was less than 0.05.

Results

Posttransplantation IL-6 elevation patterns were classified into four groups (schematic configurations are illustrated in Figure 1).

Group 1

In group 1, serum IL-6 remained negative throughout the monitoring period ($n = 1$; 6%). The 1 patient in this category has no significant elevation of serum IL-6 and no infection or rejection episodes during the monitoring period.

Fig 1. Scheme of interleukin 6 (IL-6) elevation in four groups: group 1, no significant IL-6 elevation; group 2, several spikes with normal baseline; group 3, consistently high serum IL-6 levels; group 4, some spikes with high IL-6 baseline.

Fig 2. Posttransplantation interleukin 6 (IL-6) monitor pattern of a patient in group 2. (AR I = minimal acute rejection; AR III = moderate acute rejection.)

Group 2

Group 2 consisted of patients with several sharp spikes of IL-6 elevation with normal baseline ($n = 9$; 53%). A total of 19 sharp spikes were observed in the 9 patients in this group, 13 of which (68%) were associated with the presence of rejection episodes. There were 14 histopathologically or clinically diagnosed rejection episodes, 13 of which showed an IL-6 elevation (93%). Interestingly, an elevation of serum IL-6 level was noted 3 days before the histopathological diagnosis in 3 patients and 2 days before diagnosis in another 3 patients. The other 5 serum IL-6 spikes were observed 1 day before diagnosis, and 2 spikes, coincidentally, were observed after the day of rejection diagnosis. In addition, a sharp elevation of serum IL-6 was observed in 4 instances; 3 with acute bronchitis and 1 with diffuse alveolar damage. Two spikes of serum IL-6 level did not correlate with the presence of any significant clinical rejection episodes (biopsy was not performed). The IL-6 monitoring pattern of 1 patient in this group is demonstrated in Figure 2.

Group 3

Posttransplantation serum IL-6 levels remained consistently high in 3 patients (18%); 1 suffered from cytomeg-

Fig 3. Posttransplantation interleukin 6 (IL-6) monitor pattern of a patient in group 3. (AR I = minimal acute rejection.)

Fig 4. Posttransplantation interleukin 6 (IL-6) monitor pattern of a patient in group 4. (AR III = moderate acute rejection; DAD = diffuse alveolar damage.)

alovirus infection, 1 from toxic megacolon, and 1 from repeated bacterial infections including bronchitis and pneumonia. The posttransplantation IL-6 configuration of the patient who suffered from toxic megacolon is demonstrated in Figure 3.

Group 4

Group 4 patients had several sharp spikes of serum IL-6 elevation with abnormally high IL-6 baseline ($n = 4$; 24%). All 4 patients suffered from severe pneumonia, which resulted in serious posttransplantation complications: 2 received retransplantation, 1 of whom died 21 days after transplantation. The 2 remaining patients who did not receive retransplantation died; 1 at 3 weeks and 1 at 3 months after transplantation. The posttransplantation IL-6 pattern of 1 patient is illustrated in Figure 4.

Results Summary

The postoperative features of the four groups are summarized in Table 2. It should be noted that 3 patients in group 4 died, whereas there were no deaths within 3 months in any of the other groups. In addition, the average intensive care unit stay for patients in groups 3

Table 2. Posttransplantation Statistics According to Serum Interleukin 6 Elevation Pattern

and 4 was significantly longer than for those in group 1 or 2 ($p < 0.01$).

Comment

Interleukin 6 is produced principally by activated T lymphocytes and macrophages, although some levels of IL-6 are produced by endothelial cells and fibroblasts [10]. The production of IL-6 by T lymphocytes requires the presence of macrophages, whereas macrophages alone can produce IL-6 [11]. T lymphocytes, which require an antigen presentation by macrophages, play a significant role in mediating cellular rejection in lung transplantation [2]. However, IL-6 production by macrophages reaches its peak within a few hours after antigen challenges, whereas it takes 2 days for T lymphocytes to secrete significant levels of IL-6 [11]. In addition, the T lymphocyte activation process requires the presence of IL-6, which is primarily produced by macrophages [12]. Alveolar macrophages play a crucial role in defending the host immune system, particularly in an acute phase of inflammation [13]. Therefore, we assumed that an elevation in serum IL-6 in lung recipients reflects a level of macrophage activation that could be triggered by infection or acute cellular rejection.

This study revealed three primary patterns of IL-6 level elevation in lung transplant recipients: sharp and spike-like, continuous, and a combination of the two. A spike-like IL-6 elevation was associated with presence of histopathologically proven or clinically suspected rejection, whereas a continuous elevation pattern correlated with the presence of infection. A combination of the two patterns indicated the presence of severe pneumonia and a poor prognosis. Thus, posttransplantation IL-6 configuration appears to have an association with clinical outcome for lung transplant patients. However, it should be noted that meticulous posttransplantation IL-6 monitoring is essential in making a differential diagnosis because spike elevation and continuous elevation must be distinguished.

A sharp IL-6 spike could have predictive value in diagnosing an acute cellular rejection. Of 13 IL-6 spikes associated with acute rejection in group 2, a majority were observed before the actual clinical diagnosis of rejection. Three spikes occurred in 3 days, 3 in 2 days, and 5 were 1 day before the actual diagnosis of rejection. There were reports that the other cytokines such as tumor necrosis factor α were produced at the time of cellular rejections in kidney or liver grafts [14, 15] and that soluble IL-2 receptors were clearly detectable during rejection episodes in lung transplant recipients [16]; however, there was no predictive value. Based on our earlier study [10] and the kidney transplant study [17], IL-6 monitoring could be more useful than other cytokine monitoring because the majority of serum IL-6 elevations were detectable before the actual diagnosis of rejection. In fact, messenger RNA of IL-6 was clearly demonstrated in the very early phase of rejection in the rat lung transplant model [18].

Six spikes were observed without the clear presence of

rejection episodes: 3 in conjunction with acute bronchitis, 1 with diffuse alveolar damage, and 2 without significant clinical episodes. If the study were focusing only on diagnosing rejection, these would be false positives. However, it should be noted that four instances of sharp IL-6 elevation reflected macrophage activation. The remaining two spikes could merely be false positive, but there is a possibility that they might reflect subclinical macrophage activation. Interestingly, in 3 patients with acute bronchitis, the presence of infection did not necessarily produce a consistently high level of IL-6, probably because the infections were mild and easily treatable.

The longer intensive care unit stay required for patients with persistent high levels of serum IL-6 must be explained by the fact that they suffered from severe pneumonia with extremely activated alveolar macrophages.

In summary, meticulous monitoring of the posttransplantation configuration of IL-6 levels provides some predictive value in diagnosing rejection or infection in lung transplant recipients.

This study was supported in part by a grant from the University of Pittsburgh Pathology Education and Research Foundation.

Upper Gastrointestinal Dysmotility in Heart-Lung Transplant Recipients

John Au, FRCS(Edin), Terry Hawkins, BSc, Christopher Venables, FRCS, Graham Morritt, FRCS, Christopher D. Scott, MRCP(UK), Alistair D. Gascoigne, MRCP(UK), Paul A. Corris, FRCP, Colin J. Hilton, FRCS, and John H. Dark, FRCS

Recipient pneumonectomy and the necessity for meticulous hemostasis in heart-lung transplantation can result in injury to the vagus nerves as they course through the posterior mediastinum, with consequent delay in gastric emptying. This has been reported to lead to chronic aspiration and associated pulmonary sequelae. To study the association between delayed gastric emptying, bronchiectasis, and bronchiolitis obliterans after heart-lung transplantation, we performed esophageal manometry, 24-hour pH monitoring, and radioisotopic gastric emptying in 10 patients who underwent heart-lung transplantation. Three patients had grossly delayed liquid and solid emptying that was compatible with complete vagotomy. Six other patients had delayed liquid but normal solid emptying—an unexplained finding that is the

reverse of what one would expect from vagal injury. Two of these 9 patients had esophageal dysmotility, but none demonstrated gastroesophageal reflux. One remaining patient had faster than normal gastric emptying for both solids and liquids. Of the 10, 2 patients have radiologic changes of bronchiectasis and 3 have biopsy evidence of obliterative bronchiolitis. There is no relationship between these sequelae and the occurrence of esophageal dysmotility, gastroesophageal reflux, or vagotomy. We conclude that gastric emptying abnormalities can occur after heart-lung transplantation, but such abnormalities are not associated with gastroesophageal reflux and the development of pulmonary sequelae, as previously reported.

(*Ann Thorac Surg* 1993;55:94–7)

Combined heart-lung transplantation is now an accepted modality of treatment for end-stage pulmonary vascular and selected chronic lung diseases. The importance of preserving the phrenic, vagus, and recurrent laryngeal nerves during recipient cardiopneumectomy was emphasized in the early reports [1, 2]. Nevertheless, postoperative esophageal dysmotility and delayed gastric emptying have been reported [3, 4], and there is speculation that these sequelae may predispose to chronic aspiration and consequent pulmonary sepsis. To further define the nature and effect of vagal denervation in heart-lung recipients, we have studied 10 patients by esophageal manometry, ambulatory 24-hour pH monitoring, and radioisotopic gastric emptying.

Material and Methods

From June 1988 to July 1991, 25 heart-lung transplantations were performed at our institution. The operative technique employed has been reported elsewhere [1]. Seventeen patients are currently alive. All were invited to take part in the study but only 10 gave informed consent. Patient details are given in Table 1.

Accepted for publication April 22, 1992.

Symptomatology was assessed by direct interview with the patients and completion of a standard questionnaire. Aspiration was diagnosed by classic symptomatology, the presence of foreign material during transbronchial biopsy, or both.

Esophageal manometry was performed as previously described [5], using a Gaeltec six-channel esophageal strain-gauge transducer.

Twenty-four-hour pH was monitored with a Synectics Medical 2.1-mm monocrystalline antimony pH catheter introduced nasogastrically and positioned 5 cm above the gastroesophageal junction. Intraluminal pH was recorded by a Synectics Medical Mk 2 Digitrapper at 30-second intervals. Data were downloaded into an IBM PS/2 computer and analyzed by the EsopHogram software package (version 5.50C2; Gastrosoft Inc, TX). Results were expressed in terms of the length and severity of reflux episodes, and whether they were acid or alkaline in nature.

Radioisotopic gastric emptying studies were performed after oral administration of technetium 99m-radiolabeled liquid (12 MBq) and solid (12 MBq) test meals on consecutive days. Patients fasted and then were placed in a standard, reproducible anteroposterior upright position with the large field of view gamma camera centered over the abdomen. The liquid test meal consisted of 150 mL of radiolabeled lactulose solution as a nonabsorbable

Table 1. Details of Heart-Lung Transplant Recipients

Patient No.	Age (y)	Sex	Diagnosis	Survival (mo)	Surgical Complications

CHD = congenital heart disease; PPH = primary pulmonary hypertension.

marker. A radiolabeled scrambled egg, toast, and tea meal of 400 calories was used for the solid meal. Images were collected into a 64 × 64 computer matrix. Forty sequential images each of 1-minute duration were used for the liquid gastric emptying study. The solid emptying phase was measured at intervals for up to 4 hours after ingestion.

Data analysis used regions of interest drawn around the gastric activity. Time activity curves were derived with correction for radioactive decay. Corrections for radiation attenuation arising from translocation of the meal were not made. The relatively small meal mass and the normal/lean build of the subjects were considered justification for avoiding this potentially cumbersome correction factor [6]. The time activity curves were analyzed to determine the half-emptying time as the simplest measure of dynamic emptying. The measured half-times were compared with the department's established control ranges: liquid phase, 16 to 36 minutes, and solid phase, 110 to 230 minutes. Where half-emptying was not achieved within the control range for liquids, the actual percentage emptied at 36 minutes was determined.

Chest roentgenograms and transbronchial biopsies were independently reported by a radiologist and pathologist, respectively. Transbronchial biopsy is performed either on clinical indication or routinely on postoperative days 7 and 28 and at 3-monthly intervals thereafter. Hence, all patients were studied within 3 months of their last biopsy. Bronchiectasis was defined as the presence of increased lung markings, "tramlining," cystic changes, and associated collapse, fibrosis, or consolidation on the chest roentgenogram [7] or computed tomographic scan.

Results

Flatulence (7/10), nausea (7/10), and gastroesophageal reflux (6/10) were common early postoperative symptoms, which necessitated treatment with prokinetic agents in 5 patients, with clinical improvement. By contrast, aspiration (3/10), chronic cough (4/10), dysphagia (3/10), and heartburn (0/10) were less common.

Three patients had grossly delayed liquid and solid

emptying on radioisotopic gastric emptying that was compatible with complete vagotomy. Of the 3, 1 demonstrated uncoordinated esophageal contractions and failure of relaxation of the lower esophageal sphincter on barium swallow, and none had gastroesophageal reflux on 24-hour pH monitoring (Table 2). All 3 patients complained of dysphagia in the early postoperative period, but none suffered from aspiration or chronic cough. Postprandial nausea, flatulence, bloating, and vomiting were frequent symptoms: 2 patients required pyloroplasty for relief whereas symptoms resolved with prokinetic agents and the passage of time in the third.

The 7 remaining patients had no evidence of vagal injury on radioisotopic gastric emptying: 6 had delayed liquid but normal solid emptying—an unexplained finding, which is most unusual and the reverse of what one would expect with vagotomy. One had faster than normal gastric emptying (see Table 2). Esophageal manometry demonstrated lower two-thirds dysmotility in 1 of these patients (patient 7), and 24-hour pH monitoring showed significant gastroesophageal reflux in another (patient 4). One patient (patient 1) exhibited clinical gastric outlet obstruction postoperatively and required balloon dilation of the pylorus; this patient had intraoperative trauma to her left recurrent laryngeal nerve and presumably had concomitant vagal damage that has since recovered. Another (patient 9) underwent a negative laparotomy postoperatively for pseudoobstruction, without any apparent predisposing factors.

Of the 10 patients, 2 have radiologic changes of bronchiectasis and 3 have biopsy evidence of obliterative bronchiolitis (see Table 2). There is no obvious relationship between these sequelae and the occurrence of esophageal dysmotility, gastroesophageal reflux, or vagotomy.

Comment

Recipient pneumonectomy and the necessity for meticulous hemostasis in the posterior mediastinum during heart-lung transplantation places the vagus nerves at risk of injury, either by direct trauma or by thermal injury

from electrocautery. Anatomic considerations suggest that the vagi are most likely to be injured at or near the lung hila. Thus both nerves pass posteroinferiorly in the mediastinum to reach the posterior surface of the corresponding lung root; the right nerve in direct apposition to the trachea, the left in the interval between the common carotid and subclavian arteries initially and then on the left side of the aortic arch, posterior to the phrenic nerve. At the lung root each nerve gives branches to the pulmonary plexuses and then divides into two or more branches that pass inferomedially to unite with the corresponding branches of the opposite vagus to form a plexus surrounding and supplying the esophagus [8]. Complete vagotomy during heart-lung transplantation is therefore only possible at or above the lung roots, before the division of the vagi, and most likely just above the level of the carina, where the recipient trachea is transected.

It is known from the early days of peptic ulcer surgery that complete vagotomy results in prolonged gastric atonia [9], hence the need for drainage procedures. Three of our patients were found on radioisotopic gastric emptying studies to have profound gastric paresis compatible with complete vagotomy, 2 of whom required a drainage procedure for the relief of symptoms.

Six of the remaining 7 patients demonstrated a curious pattern of delayed liquid but normal solid gastric emptying that is incompatible with complete or partial vagotomy. Classically, partial vagotomy results in enhanced liquid but delayed solid emptying. By disrupting receptive relaxation, vagotomy raises intragastric pressure and causes more rapid emptying of liquids, which is dependent on the pressure gradient between the stomach and the duodenum. By disturbing antral motility, solid emptying is retarded [10, 11]. The combination of delayed liquid but normal solid gastric emptying has been reported in elderly subjects [12]; its mechanism and significance in our patients is unexplained.

The physiologic consequences of vagotomy at the carinal level on esophageal function may be inferred from animal experiments. It is well established that the function of the striated esophagus is completely dependent on

its vagal supply, whereas that of the smooth muscle part is largely dependent on its intrinsic neural plexus [13]. At the carinal level, the esophagus is composed of a varying proportion of striated and smooth muscle [14], and the effect of vagotomy is presumably dependent on the amount of striated muscle present. It is interesting that the only patients in this series who complained of dysphagia in the early postoperative period were the 3 who had evidence of complete vagotomy. Of the 3, only 1 (patient 10) has objective evidence of esophageal dysmotility. One other patient (patient 7) has asymptomatic esophageal dysmotility but no evidence of vagotomy; this is perhaps a coincidental finding.

The tone of the lower esophageal sphincter is partly due to myogenic properties and partly due to neural and hormonal influences. Vagotomy in dogs and cats affects lower esophageal sphincter function variably and may lead to decreased resting tone or spasm [13]. Some evidence exists to suggest that delayed gastric emptying in humans may predispose to gastroesophageal reflux [15, 16], although data from vagotomized animals and other clinical studies are conflicting [10, 17-19]. Twenty-four-hour pH monitoring showed no evidence of gastroesophageal reflux in any of our patients with evidence of vagotomy or delayed gastric emptying; ironically, 1 patient with normal gastric emptying had free gastroesophageal reflux, but this is, again, perhaps a coincidental finding.

Our results conflict with those reported by Reid and associates [4], who reported a high incidence of chronic cough and delayed gastric emptying, esophageal dysmotility, or both in their patients. This was associated with evidence of aspiration and bronchiectasis. Five patients in our series reported chronic cough and aspiration as symptoms, none of whom have radiological changes of bronchiectasis. Of the 3 patients with gastric paresis, 2 did not have substantiated gastroesophageal reflux (1 refused pH monitoring), and none have bronchiectasis (see Table 2). The 2 patients who do have bronchiectasis in our series have both had life-threatening postoperative suppurative pneumonia but no evidence of gastroesophageal reflux.

Finally, the only patient who has significant gastroesophageal reflux has no evidence of bronchiectasis. This discrepancy between our observations and those of Reid and associates may partly be explained by the fact that their investigations were performed on a selected group of symptomatic patients. It is also not clear from their report whether "delayed gastric emptying" implied delayed liquid or solid emptying, or both. Furthermore, the diagnosis of delayed gastric emptying in 2 of their patients was based on barium studies, despite normal radioisotopic gastric emptying. Barium estimates of gastric emptying are known to be qualitative at best and misleading at worst [11, 20].

We conclude that there is evidence of esophageal dysmotility and delayed gastric emptying compatible with complete vagotomy in heart-lung recipients; this finding is not correlated with gastroesophageal reflux, chronic aspiration, or the development of bronchiectasis postoperatively. Nevertheless, vagal injury has been a source of early morbidity in these patients, with 3 of our 17 long-term survivors requiring some form of intervention. Modifications to surgical technique that may decrease the risk of vagal injury and improve morbidity include circumpect use of diathermy when securing hemostasis in the posterior mediastinum, and the stapling technique of Vouhe and Darteville [21], in which dissection of the posterior mediastinum is limited. The risk of vagal injury may also be minimized in the alternative operation of bilateral sequential lung transplantation for patients with septic lung disease, in which dissection of the distal trachea, subcarinal region, and posterior mediastinum is avoided [22].

This project was supported by a grant from the Freeman Hospital Heart Transplant Research Fund. We are indebted to Sister J. Watson for her assistance in performing the 24-hour pH studies, to S. Farr for his assistance in performing the esophageal manometry, and to H. Brown, S. Hughes, C. McCubbing, and D. Baldwin for their assistance with the radioisotopic gastric emptying studies.

Surgical Management of Thrombotic Disc Valve

Kuei-Ton Tsai, MD, Pyng Jing Lin, MD, Chau-Hsiung Chang, MD, Jaw-Ji Chu, MD, Jen-Ping Chang, MD, Chiung-Lun Kao, MD, and Ming-Jang Hsieh, MD

Division of Thoracic and Cardiovascular Surgery, Chang Gung Memorial Hospital, Taipei, Taiwan, Republic of China

Thrombotic obstruction, a rare but often fatal complication of cardiac valve prostheses, appears to occur more frequently in tilting-disc valves than in other valve designs. Its diagnosis and surgical treatment remain a challenge. Ten consecutive patients who had thrombosis of a tilting-disc valve prosthesis were treated in Chang Gung Memorial Hospital from November 1982 to August 1990. Preoperative clinical features, including exertional dyspnea, new murmur, and absence of a metallic click from the prosthetic valve, occurred in all of the patients. Symptoms were present for 1 week or more before reoperation in 70% of the patients; nevertheless, many patients were referred only after acute exacerbation of heart failure and development of pulmonary edema. Echocardiography confirmed prosthetic valve malfunction in 90% of the patients. One unconfirmed case was

later documented by cardiac catheterization. Anticoagulant therapy was in the therapeutic range for only half of the patients at the time of admission. Prompt reoperation was performed for thrombectomy (8 patients, all survived) or valve replacement (2 patients, one death). Long-term outcome was satisfactory in all survivors with a mean follow-up of 31.6 months. These findings emphasize the importance of considering the diagnosis of thrombosis in patients with mechanical heart valve prostheses who are first seen with nonspecific symptoms and minor changes of their physical findings. The diagnosis could be easily made by echocardiography. Thrombectomy is an easy, fast, and safe procedure, especially for these critically ill patients.

(Ann Thorac Surg 1993;55:98-101)

Thrombotic obstruction is a rare but often fatal complication of cardiac valve prostheses. This kind of complication occurs more frequently in tilting-disc valves than in other kinds of prostheses [1-15]. Björk and Henze [16] reported that sudden thrombosis in the absence of anticoagulation occurs at the rate of about 3% per year. Even with anticoagulation, 1% of patients with a tilting-disc valve in the mitral position may have this complication. Karp and associates [12] reported the cumulative (actuarial estimate) risks for thrombosis of tilting-disc valves to be 3%, 13%, and 13% at 5 years after aortic, mitral, and combined aortic and mitral valve replacement, respectively; overall incidence was 8.6%.

Surgical treatment of disc valve thrombosis includes both thrombectomy and replacement of the prosthetic valve [9, 17-20]. In this report, we describe the entire series of reoperations for thrombotic obstruction of prosthetic tilting-disc valves at this hospital.

Material and Methods

We retrospectively reviewed the clinical records of all patients who sustained thrombus formation on prosthetic tilting-disc valves and underwent reoperation for malfunctioning disc valves at the Chang Gung Memorial Hospital. Data from 10 consecutive patients from November 1982 to August 1990 were collected.

Accepted for publication April 23, 1992.

Address reprint requests to Dr Lin, Division of Thoracic and Cardiovascular Surgery, Chang Gung Memorial Hospital, 199, Tun-Hwa North Rd, Taipei, Taiwan, Republic of China.

Results

Clinical data on the 10 patients are summarized in Table 1. All patients had initial valve replacement at Chang Gung Memorial Hospital. Thrombotic obstruction of the prosthetic valve occurred in the aortic position in 6 patients and in the mitral position in 4 patients. Nine patients had Björk-Shiley tilting-disc valves (five aortic, four mitral), whereas the remaining patient had a Sorin valve (aortic).

The interval between implantation and dysfunction of the disc valve ranged from 2 to 121 months (mean, 43 months). At admission, systemic anticoagulation with warfarin sodium seemed to be adequate (prothrombin time ≥ 1.5 and 2.0 times control in aortic and mitral prostheses, respectively) in 5 of the 10 patients at the time of diagnosis of disc valve thrombosis. However, warfarin had been discontinued occasionally in these 5 patients. In the remaining patients, warfarin was discontinued or used only intermittently. In these patients, the prothrombin time was nearly normal when the symptoms of congestive heart failure developed. None of the patients took antiplatelet agents in our series.

Prominent preoperative symptoms included dyspnea in all 10 patients and angina in 3 patients. Furthermore, 1 patient had had a recent transient neurological deficit and a seizure attack.

The duration of progressing cardiac symptoms before reoperation varied widely: less than 1 week, 3 patients; 1 week to 1 month, 4 patients; 1 to 6 months, 1 patient; and more than 6 months, 2 patients. At the time of the operation, the New York Heart Association classifications

were class IV for 6 patients, class III for 3 patients, and class II for 1 patient.

Three patients were in cardiogenic shock at the time of valve reoperation. However, these 3 patients, as well as the other symptomatic patient, had milder symptoms for periods ranging from 2 days to 1 year preoperatively. These minor symptoms were initially diagnosed as a flu-like illness, chronic obstructive lung disease, or mild congestive heart failure due to progressive left ventricular dysfunction.

The diagnosis of prosthetic valve malfunction was suspected from clinical examination and various laboratory evaluations. A new murmur developed in all 10 patients, in whom a decrease to absence of the metallic click of the prosthetic valve was also detected. Other physical findings included hypotension in 4 patients, 3 of whom were in overt cardiogenic shock. In addition, 1 patient denied serious cardiac limitation but was noted to have severe hemolytic anemia at the time of routine follow-up. The results of the physical examination, however, suggested valve malfunction.

Diagnostic studies included chest roentgenography, the results of which were abnormal in all 10 patients. Abnormal findings were pulmonary venous congestion or cardiomegaly. Fluoroscopy with cineradiography, an important and noninvasive diagnostic tool, was not available for analysis because the results were not formally recorded. Furthermore, echocardiograms were obtained from all 10 patients. Nine patients were thought to have findings indicative of prosthetic valve dysfunction, and reoperations were scheduled without further diagnostic delay. These positive findings included restricted disc excursion with decreased opening and closing rates, increased echodensity over the prosthetic valve, and abnormally high transvalvular pressure gradient and maximal velocity. For the only patient with unconfirmed diagnosis, cardiac catheterization was performed, and prosthetic valve dysfunction was confirmed by documentation of valvular incompetence and delineation of disc mobility.

The timing of reoperation depended on the time necessary for establishing the correct diagnosis of thrombotic

obstruction of the prosthetic valve. The period from hospital admission to operation was more than 1 day for 8 patients, and only 2 patients underwent operation within 24 hours. However, emergency operations were performed in all patients once the diagnosis was established. Simple thrombectomy without valve replacement was performed on 8 patients under cardiopulmonary bypass. The thrombotic prostheses were approached from both sides through a left atriotomy and aortotomy. The thrombotic material was removed manually using angled forceps and open-tipped suction [17]. The disc mechanism was rotated to clear all quadrants (except in patient 10, whose prosthesis was unrotatable). A laryngeal mirror was also employed to ensure that all the thrombus was cleaned off. The disc mechanism was found to be free from any mechanical impairment. At termination of this procedure the disc mechanism was aligned so that the disc had free motion. The other 2 patients (patients 1 and 4) received valve replacement with a Carpentier-Edwards prosthesis due to poor compliance with the warfarin regimen and the preference of the patients. The aortic cross-clamp time was significantly different between the replacement group (51 ± 4 minutes) (mean $\pm$ standard error of the mean) and the thrombectomy group (31 ± 2 minutes) ($p < 0.01$).

All but 1 of the patients had an uncomplicated postoperative course and was discharged uneventfully. The only hospital death occurred in a patient (patient 4) who sustained persistent low cardiac output despite replacement of the obstructed valve.

All the survivors were closely followed up; follow-up time ranged from 5 to 101 months with a mean of 31.6 months. There were no late thromboembolic episodes during the follow-up period. Excellent prosthetic valve function was demonstrated by echocardiographic studies. All patients were in New York Heart Association class I or II. Anticoagulant (warfarin sodium) was prescribed to patients receiving thrombectomy. Prothrombin time was maintained from 1.5 to 2.0 or 2.0 to 2.5 times control for aortic or mitral prostheses, respectively.

Comment

The reported incidence of Björk-Shiley valve thrombosis ranges from 1% to 8% [1-15]. Reports have emphasized the sudden, precipitous deterioration in hemodynamics and high mortality after reoperation in these critically ill patients [21]. However, Kontos and colleagues [22] found that nonspecific symptoms were present for 1 week or more before reoperation in 86% of their patients. In this review the chronicity of the symptoms before presentation was also elucidated. Seventy percent of the patients had clinical evidence of valve dysfunction for 1 week or more before reoperation; many of these patients had acute deterioration just before hospital admission. These results are especially pertinent for physicians who are responsible for the follow-up of patients with prosthetic valves. Relatively minor symptoms, especially pulmonary congestion, should prompt a careful cardiac examination to exclude the possibility of prosthetic valve thrombosis. Change to absence of the prosthesis-related metallic click was the most significant finding. Other nonspecific clinical findings include systolic and diastolic murmurs and hemolytic anemia.

Echocardiography combined with Doppler studies remained the first-line diagnostic procedure for documentation of prosthetic valve thrombosis in this institute because of its convenience and noninvasiveness. All 10 patients received this examination soon after admission, and high accuracy was exhibited, with 9 of the 10 patients showing positive findings indicating valve dysfunction. Although fluoroscopy with cineradiography in two simultaneous planes has been shown to increase the accuracy of detecting disc valve dysfunction [23], an unacceptably high false-negative rate of 64% was still noted in the Kontos series [22]. This fluoroscopy technique was not routinely used in our series. Cardiac catheterization, despite continuing to be the most sensitive diagnostic procedure in the evaluation of a patient who is suspected of having prosthetic valve thrombosis [9], was reserved for the patient with unconfirmed diagnosis by echocardiography because of its invasiveness and even danger to these hemodynamically crippled patients.

Inadequate systemic anticoagulation had been reported to be the main cause of the thrombosis [19, 24]. In our and Kontos' series [22], however, half of the patients were documented to have had adequate anticoagulation at the time of admission. Nevertheless, occasional discontinuation of anticoagulant therapy at some time in the patient's history were noted and this might have been associated with a rebound hypercoagulable state, which has been reported to result in an increased rate of thromboembolic complications [25].

Surgical treatment of disc valve thrombosis includes both thrombectomy and replacement of the prosthetic valve [9, 17-20]. Thrombectomy was considered to be the procedure of choice in our series because of its ease and rapidity—that is, it is a safe procedure in these critical conditions. The thrombus could be easily removed from both sides of the valve through a left atriotomy and aortotomy.

In contrast to the reported mortality from prosthetic valve thrombosis ranging from 33% to 100% [3, 5, 7-9, 11, 12], a mortality rate of 10% was noted in this series. We would like to stress the importance of close observation of any patient with a mechanical heart valve, especially a tilting-disc prosthesis, who is seen with nonspecific cardiac symptoms. A thorough evaluation to rule out the possibility of thrombotic obstruction of the prosthesis should be performed. For most patients, early reoperation will give the best results. Thrombectomy is an easy, fast, and safe procedure for these critical patients. In patients who are in stable condition preoperatively, operative mortality is low.

Improved Recovery of Immature Myocardium With L-Glutamate Blood Cardioplegia

Paul W. Weldner, MD, John L. Myers, MD, Cynthia A. Miller, BS, Juan D. Arenas, MD, and John A. Waldhausen, MD

Department of Cardiothoracic Surgery, College of Medicine, Pennsylvania State University, Hershey, Pennsylvania

Enhancement of myocardial recovery with glutamate-enriched cold blood potassium cardioplegia (BPC) was evaluated using an isolated working heart model. Three groups of hearts from immature rabbits were subjected to 20 minutes of warm (37°C) ischemia to allow energy depletion, followed by 90 minutes of hypothermic (10°C) ischemia. Myocardial protection provided during hypothermia consisted of cardioplegia infusion, at 50 mm Hg every 30 minutes at 4°C, of either St. Thomas' Hospital solution (group 1, $n = 6$), oxygenated BPC (group 2, $n = 7$), or oxygenated BPC enriched with 20 mmol/L L-glutamate (group 3, $n = 7$). Percent recovery of aortic flow was $87.6\% \pm 6.3\%$ (results expressed as mean $\pm$ standard error of the mean) in group 3, which was significantly

better than for either group 1 ($63.4\% \pm 4.0\%$) or group 2 ($47.0\% \pm 3.5\%$) ($p < 0.05$ by analysis of variance). Group 3 hearts had significantly better recovery of myocardial energy stores ($\mu\text{mol/g}$ dry weight) compared with group 1 or 2 hearts: adenosine triphosphate, 17.8 ± 1.1 versus 12.4 ± 1.5 and 12.1 ± 0.4 ; creatine phosphate, 25.9 ± 1.8 versus 17.8 ± 1.8 and 20.3 ± 0.7 ; and glycogen, 140.7 ± 12.6 versus 98.7 ± 9.9 and 60.7 ± 9.9 ($p < 0.05$). Glutamate-enriched BPC provided excellent myocardial protection after ischemia in this immature model, and this study quantitatively supports the use of glutamate-enriched BPC in neonatal clinical practice.

(*Ann Thorac Surg* 1993;55:102-5)

In an effort to improve myocardial function after cardiac operations, much research has centered on optimizing cardioplegic solutions. Cold blood potassium cardioplegia with a normal calcium concentration together with topical hypothermia has been shown to offer superior protection over crystalloid cardioplegia and hypothermia [1], probably because blood cardioplegia delivers a superior buffering capacity provided by the histidine portion of the hemoglobin molecule. Evaluation of the myocardial protective properties of amino acids, particularly glutamate, in cardioplegic solutions stemmed from investigations into the source of anaerobic energy production in the musculature of diving mammals [2]. Postulated biochemical pathways utilizing Krebs cycle intermediate compounds including glutamate and aspartate were established, allowing for anaerobic production of energy and maintenance of the cellular redox potential.

Rosenkranz and associates [3] found that glutamate-enriched blood cardioplegia improved myocardial recovery in an adult canine model. However, neonatal myocardium responds differently to ischemia than does adult myocardium due to differences in structure, function, and metabolism [4]. Therefore, experience gained with myocardial preservation in the adult cannot automatically be

applied to the neonate. The goal of this study was to determine the effect of glutamate enrichment to blood cardioplegia on the functional and metabolic recovery of immature energy-depleted myocardium.

Material and Methods

Hearts from immature (3 to 4 weeks; mean weight, 521 g; range, 467 to 590 g) rabbits were studied. Anesthesia was induced with 4% halothane. Heparin (500 mg/kg), pentobarbital (30 mg/kg), and pancuronium bromide (0.1 mg/kg) were given intravenously. Each heart was excised and weighed. The aorta was cannulated and then connected to the isolated working heart apparatus with retrograde aortic (Langendorff) perfusion initiated from a reservoir 60 cm above the heart. The pulmonary veins were ligated, excess mediastinal tissue was trimmed, and the left atrium was cannulated for conversion to the working heart model. All animals received humane care in compliance with the Society for Medical Research and the Guide for the Care and Use of Laboratory Animals prepared by the National Academy of Sciences and published by the National Institutes of Health (NIH publication No. 85-23, revised 1985).

Working Heart Model

An isolated working heart model was used, as described by Neely and associates [5]. To begin the working heart mode, Langendorff perfusion was stopped and the left atrium was filled with oxygenated Krebs-Henseleit buffer. The heart ejected the fluid through the aortic cannula into a chamber with an adjustable resistance to flow. The

Accepted for publication April 24, 1992.

Presented at the meeting of the Association of Academic Surgeons, Colorado Springs, CO, Nov 20-23, 1991.

aortic pressure can be raised by increasing the resistance to flow; therefore, aortic flow and mean aortic pressure are inversely related.

The coronary arteries were perfused by the cardiac output generated by the left ventricle. Coronary return was ejected from the right ventricle and collected and recirculated with the aortic flow. Left atrial pressure was adjusted by altering the height of the left atrial reservoir. To induce ischemia, the left atrial perfusion was stopped and the aortic outflow channel was clamped. Cardioplegic solution was infused into the aortic root through a separate cannula.

The Langendorff perfusate consisted of a modified Krebs-Henseleit buffer equilibrated with 95% oxygen and 5% carbon dioxide, with a pH of 7.4 at 37°C. The composition (in mmol/L) of the buffer was as follows: NaCl, 118; KCl, 4.7; CaCl₂, 2.5; MgSO₄, 1.2; KH₂PO₄, 1.2; Na₂EDTA, 0.5; NaHCO₃, 25; and glucose, 11.1. The working solution was identical, with the exception of the addition of insulin (2.5 U/L) and bovine serum albumin (to a final concentration of 0.2%). Oxygen tension in both the Langendorff and working perfusates ranged from 475 to 525 mm Hg.

Experimental Sequence

After the heart was mounted on the aortic cannula, the following sequence was followed: 10 minutes of Langendorff perfusion; a 15-minute working period; 20 minutes of warm (37°C) ischemia (to produce energy depletion); 90 minutes of hypothermic (10°C) ischemia; 10 minutes of Langendorff reperfusion; and a second 15-minute working period.

Myocardial Preservation

Three methods of myocardial preservation were evaluated during the 90-minute period of hypothermia: in group 1, 6 hearts received a 10-mL/kg body weight infusion of St. Thomas' Hospital crystalloid cardioplegia (Plegisol; Abbott Laboratories, Chicago, IL) at 4°C every 30 minutes at 50 mm Hg; in group 2, 7 hearts received an infusion of oxygenated blood potassium cardioplegia at 4°C for 2 minutes at 50 mm Hg every 30 minutes; and in group 3, 7 hearts received an infusion of oxygenated blood potassium cardioplegia enriched with 20 mmol/L of L-glutamate (monosodium glutamate) also at 4°C for 2 minutes at 50 mm Hg every 30 minutes. With each method, myocardial temperature was maintained at 10°C by immersion in a cold saline bath. The cardioplegia was delivered according to the current clinically used methods, crystalloid cardioplegia based on weight of patient, blood cardioplegia based on timed delivery.

The blood cardioplegia was prepared by mixing an initial solution to blood (obtained from adult rabbit donors) in a ratio of 1:4. The initial solution contained per liter: 10 g of glucose, 3.6 g of KCl, 1.2 g of NaCl, 5.0 g of Tris-buffer, 2 mL of 3% papavarine, and 20 U of insulin. The basic indices of the blood cardioplegia were 16 mEq K⁺/L, 100 mEq Na⁺/L, pH of 7.8 (37°C), osmolality of 330 mOsm/L, hematocrit of 0.25, and temperature of 9°C. The blood cardioplegia was continuously circulated, filtered with a 40-μm Pall blood transfusion filter (Pall Biomedical

Inc, Fajardo, PR), and oxygenated using a Sarns Pediatric Membrane Oxygenator (Sarns Inc/3M, Ann Arbor, MI) to an oxygen tension of 200 to 300 mm Hg. The crystalloid cardioplegia was unoxygenated and filtered through a 0.45-μm filter.

Measurement of Myocardial Preservation

Aortic flow was measured by timed collections from the aortic ejection line. Systolic, diastolic, mean aortic, and left atrial pressures were continuously measured with a disposable transducer and recorded on a Siemens System Sirecust 400 monitor. Heart rate was determined by a timed count. The hemodynamic parameters measured during the second working period were compared with those obtained during the first working period. The results were expressed as the percent recovery of the preischemic value.

After completion of the second working period, the hearts were frozen with tongs precooled in liquid nitrogen for later determination of myocardial high-energy phosphate stores. To obtain baseline and energy-depleted values, 6 additional hearts were frozen after the first working period and 6 more after the warm ischemic period. The samples were then stored in a liquid nitrogen tank (-196°C) until assays for adenosine triphosphate (ATP), creatine phosphate, and glycogen, using standard enzymatic spectrophotometer procedures, were performed.

Statistical Analysis

Data are reported as mean ± standard error of the mean. One-way analysis of variance was used to determine statistical differences in hemodynamic performance or myocardial energy stores between groups 1, 2, and 3. When a significant *F* value was identified by analysis of variance, *t* tests modified by the Student-Newman-Keul technique were performed to distinguish differences between the means.

Results

Hemodynamics

Baseline hemodynamic values are presented in Table 1. There were no significant differences among the groups of rabbit hearts before ischemia.

The percent recovery of hemodynamics after ischemia is presented in Table 2. The hearts preserved with glutamate-enriched blood potassium cardioplegia (group 3) had excellent preservation of hemodynamics when compared with the hearts preserved with crystalloid cardioplegia (group 1) or unenriched blood potassium cardioplegia (group 2). The percent recovery of aortic flow, which is the major determinant of functional recovery using this model, was significantly better for group 3 hearts than for either group 1 or 2 hearts. Group 3 enriched hearts also performed significantly better than group 2 unenriched hearts with regard to recovery of systolic aortic pressure, heart rate, and coronary sinus flow. Group 1 hearts had significantly better recovery of aortic flow, systolic aortic pressure, and coronary sinus

Table 1. Preischemic Hemodynamic Values^a

Group	SAP (mm Hg)	MAP (mm Hg)	HR (beats/min)	AF (mL/min)	CSF (mL/min)
1	78.7 ± 1.6	50.8 ± 0.9	168.7 ± 12.0	75.7 ± 6.7	26.7 ± 3.0
2	82.1 ± 1.8	51.1 ± 1.5	173.7 ± 7.8	87.7 ± 8.9	23.7 ± 4.5
3	80.0 ± 2.3	50.0 ± 0.5	146.3 ± 12.0	68.3 ± 7.5	29.7 ± 2.7

^a There were no significant differences between the three groups.

flow than group 2 hearts. The amount of St. Thomas' Hospital cardioplegia delivered averaged 15 mL for group 1, in contrast to 30.9 ± 4.9 mL in the unenriched blood cardioplegia group 2 and 39.2 ± 1.1 mL in the glutamate-enriched blood cardioplegia group 3. There was no significant difference between the amount of cardioplegia delivered for group 2 and group 3.

Biochemical Preservation

Baseline, warm ischemia, and final myocardial energy stores are presented in Table 3. As expected, all three energy stores decreased after the 20-minute period of warm ischemia. However, this decrease was only significant for measurements of ATP (13.6 ± 1.3 versus 17.8 ± 0.9 $\mu\text{mol/g}$ dry weight). Group 1 and 2 hearts at the completion of the study failed to exhibit any improvement in ATP or creatine phosphate stores with further depletion of their glycogen stores to a significantly lower level when compared with baseline. Group 3 hearts had significantly higher levels of all three energy stores when compared with group 1 and 2 hearts and were comparable to baseline values.

Comment

The importance of providing optimal myocardial protection during pediatric cardiac operations has become evident from clinical studies in which up to 50% of the surgical mortality was due to inadequate myocardial protection [6]. Although topical hypothermia has been shown to offer excellent preservation of the immature heart [7], it is difficult to ensure continuous, global hypothermia during an operation in which the heart must be manipulated. Therefore, cardioplegic solutions, which have been shown to be effective in adults undergoing cardiac operations [8], have been adopted in many centers for use in pediatric cardiac operations. However, most of these solutions were developed in the laboratory using

mature animal models, and recent investigations of their effectiveness in immature models have found them to be inadequate or even detrimental [7]. Experience gained with cardioplegic protection in the adult cannot, therefore, be automatically assumed to pertain to the neonate.

The results of this study indicate that glutamate supplementation to blood cardioplegia offers excellent functional recovery of the energy-depleted immature myocardium and are in agreement with the findings of Rosenkranz and associates [3] who reported its benefit in energy-depleted adult myocardium. Group 3 glutamate-enriched blood potassium cardioplegia-protected hearts performed 24% better than group 1 crystalloid-protected hearts and 41% better than group 2 unenriched blood potassium cardioplegia-protected hearts.

The proposed mechanism whereby glutamate improves the tolerance of these energy-depleted hearts is the enhancement of glycolytic metabolism during ischemia and the improvement of oxidative metabolism after ischemia [3]. Penny and Cascarano [9], however, demonstrated that glutamate enrichment to anaerobically perfused isolated rat hearts can actually stimulate glycogenesis because there was net glycogen synthesis from control values. Our study supports Penny and Cascarano's results, with group 3 hearts containing glycogen levels that were higher than those after the warm ischemic period and that were not significantly different from baseline values. In addition to performing glycogenesis, group 3 hearts were able to replenish their high-energy phosphate stores of ATP and creatine phosphate to baseline levels. In adult energy-depleted hearts, Rosenkranz and associates [3] found glutamate to improve recovery; however, this was accompanied by depletion of ATP stores. Our study suggests that immature hearts may be more resistant to depletion of the adenine nucleotide pool with glutamate enhancement, allowing regeneration of ATP stores during reperfusion. This improved ability of the immature heart to conserve or regenerate ATP with glutamate supple-

ATP = adenosine triphosphate; CP = creatine phosphate.

mentation is supported by a clinical report by Pisarenko and colleagues [10]. They found that, during surgical correction of tetralogy of Fallot defects, there was preservation and, in some instances, increases in myocardial ATP stores in intraventricular septal biopsy specimens of hearts protected with glutamate-enriched blood cardioplegia and universal decrease in ATP stores in hearts protected with unenriched blood cardioplegia.

The biochemical recovery of group 1 and 2 hearts revealed that their ATP and creatine phosphate stores were maintained at the levels found after warm ischemia, but with further depletion of their glycogen stores. Although other studies failed to find a correlation between energy stores and functional capacity [3, 7], glycogen levels in this study appear to be a good predictor of functional recovery. The improved functional recovery of group 1 hearts over group 2 hearts also contrasts with Corno and associates' [1] results, in which functional recovery was better with blood cardioplegia than with crystalloid cardioplegia. A possible explanation is that our study used blood cardioplegia in a Langendorff isolated working heart preparation. Our blood cardioplegia circuit may need further refinement, but may emphasize even more the improved recovery seen with glutamate enrichment in this age group.

In summary, glutamate enrichment of blood cardioplegia improves both the functional and biochemical recovery of immature energy-depleted myocardium, which may simulate that seen in cyanotic heart disease. We support its use in pediatric cardiac operations, as it should improve the overall myocardial performance of these patients.

The internal mammary, musculophrenic, and superior epigastric arteries were unilaterally harvested from 11 individuals (aged 49 to 83 years; mean age, 67 years) and were examined histologically at 1-cm intervals. In 2 individuals the media of the entire internal mammary artery was elastic, whereas in the other 9 individuals we observed an alternating histological pattern in the media of the internal mammary artery, that of the proximal and distal segments being elastomuscular and that of the mid segment being elastic. In 4 of the latter 9 individuals the distal 10% to 20% of the media of the internal mammary artery was muscular with rare elastic lamellae. The media of the first 1 to 2 cm of the musculophrenic and superior epigastric arteries was elastomuscular or muscular with rare elastic lamellae, whereas more distally the media was purely muscular. The degree of intimal hyperplasia was significantly greater in arterial segments

with a purely muscular media (25.6%) than in those with elastic (16.7%), elastomuscular (15.3%), and muscular (with rare elastic lamellae) (17.5%) types of media ($p < 0.01$). The mean cross-sectional luminal area of the elastic segment (1.9 mm²) and proximal and distal elastomuscular segments (1.9 and 1.2 mm², respectively) of the internal mammary artery was significantly greater than that of the muscular segments of the musculophrenic artery (0.9 mm²) and the superior epigastric artery (0.7 mm²) ($p < 0.01$). These findings emphasize the ideal suitability of the internal mammary artery as a conduit in coronary artery bypass grafting, based on its low risk of intimal thickening and its matching caliber, contrasting with less favorable properties of the musculophrenic and superior epigastric arteries.

(*Ann Thorac Surg* 1993;55:106-13)

The properties of the internal mammary artery (IMA) as an almost ideal arterial conduit in myocardial revascularization are determined by its histological structure, which is unique in that it is the only peripheral artery in the human body that is elastic, being composed of an intima that is limited by a well-formed internal elastic lamina and a media that is formed by a network of circularly and longitudinally interlacing elastic lamellae, between which smooth muscle cells are dispersed in a spirally arranged fashion [1]. Superior long-term patency rates of the IMA graft have led to extended use of this conduit for myocardial revascularization, such as bilateral and sequential IMA grafting [2-4]. For these complex grafting schemes longer mammary pedicles are required to reach the posterior coronary circulation. This necessitates distal dissection up to and beyond the epigastric bifurcation, where the histology of the vessel wall, the degree of intimal thickening, and the luminal size may be different. Because these variables may influence the long-term patency of the IMA in aortocoronary bypass grafting, a thorough histological study of this conduit and its

continuation into the musculophrenic artery (MPA) and superior epigastric artery (SEA) with emphasis on these morphologic features is warranted.

Material and Methods

In this study the IMA was unilaterally (5 from the right side and 6 from the left side) obtained at autopsy from 11 unselected individuals, between 49 and 83 years of age (mean age, 67 years), who had died of noncardiac diseases. None of the patients had hypertension or diabetes mellitus. The IMA was harvested from its origin at the anteroinferior aspect of the first part of the subclavian artery, including a segment of 3 to 4 cm of the subclavian artery, to beyond the epigastric bifurcation, which invariably was located within the limits of the fifth to seventh intercostal spaces. The length of the IMA from its origin to the epigastric bifurcation varied from 17 to 22.5 cm (mean $\pm$ standard deviation, 19.5 $\pm$ 2.4 cm). Both terminal branches, ie, the MPA and SEA, were transected as far distal to the epigastric bifurcation as possible, varying from 3 to 6 and from 5 to 8 cm, respectively.

In all cases, the arteries were fixed in a flaccid state in 4% formaldehyde solution during 1 week. In a previous study [1] we have demonstrated that there is no signifi-

Fig 1. In the internal mammary, musculophrenic, and superior epigastric arteries the perimeters of the endothelium, internal elastic lamina, and external elastic lamina and the respective areas surrounded by these were measured.

cant difference in the width of the intima and media after fixation of muscular or elastic conduits in a flaccid state or at a pressure of 100 mm Hg. Each specimen was laminated in consecutive transverse sections at intervals of 1 cm, starting proximally at the origin of the IMA and ending at the distal segments of the MPA and SEA. Subsequently these sections were embedded in paraffin wax and prepared in 6- μ m sections. Care was taken to ensure that these sections were not oblique and were not adjacent to branching points. All sections were stained with hematoxylin-eosin and elastin-trichrome after Masson techniques.

The morphologic condition of the IMA, MPA, and SEA was studied at the aforementioned consecutive intervals, with emphasis on the histology of the media and the intima. In this scope the number of discontinuities in the internal elastic lamina and the number of elastic lamellae in the media, including the internal and external elastic laminae, were counted. In addition, the degree of presence of smooth muscle cells in the media was estimated in each section.

Subsequently, using a commercially available semiautomatic image analyzing system (MOP-Videoplan; Kontron, Munich, Germany), the perimeters of the endothelial lining (P_{endo}), the internal elastic lamina (P_{iel}), and the external elastic lamina (P_{eel}) were measured (Fig 1). In addition, the cross-sectional areas surrounded by these 3 perimeters (A_{endo} , A_{iel} , and A_{eel} , respectively) were measured. The measurements were carried out with a $\times 2.5$ neofluar objective ($NA = 0.08$). From these measured quantities the following parameters were derived:

1. Mean width of the media according to the formula:
mean width of media = $2 \times (A_{eel} - A_{iel}) / (P_{eel} + P_{iel})$
2. Density of elastic lamellae in the media according to the formula: density elastic lamellae = number of elastic lamellae/mean width of media
3. Degree of intimal hyperplasia according to the formula:
degree of intimal hyperplasia = $(A_{iel} - A_{endo}) / A_{iel} \times 100\%$

Because the IMAs varied considerably in length among the individuals we introduced the concept of relative distance. It is defined as the distance in the IMA distal to the proximal first centimeter (for the explanation of select-

ing this point, see the Morphologic Findings section) with the epigastric bifurcation being the end point, divided by the entire length of the IMA (minus its first centimeter) and multiplied by a factor of 100, which yields the distance percentage.

The differences in the cross-sectional luminal area and the degree of intimal hyperplasia in the three vessels were studied with analysis of variance. The same analysis was performed to investigate the effect of the level in the IMA on cross-sectional luminal area, the number and density of elastic lamellae, and the degree of intimal hyperplasia. Quantitative data with regard to the number of discontinuities in the internal elastic lamina were analyzed with the signed rank test. For multiple comparisons Fisher's least significant difference method was used. A p value less than 0.05 indicates a difference unlikely to be due to chance alone.

Results

Morphologic Findings

Four histological patterns were defined in the media: (1) the elastic pattern, which contains a minimum of 8 densely packed and concentrically arranged elastic lamellae, including the internal and external elastic laminae, with only moderate presence of smooth muscle cells; (2) the elastomuscular pattern, which contains a minimum of 5 and a maximum of 7 less regularly arranged elastic lamellae, including the internal and external elastic laminae, with abundant presence of smooth muscle cells; (3) the muscular pattern with rare elastic lamellae, which primarily contains smooth muscle cells and 3 or 4 irregularly arranged elastic lamellae, including the internal and external elastic laminae; and (4) the muscular pattern, in which the media consists almost purely of smooth muscle cells with some elastic fibers dispersed in between and without elastic lamellae except the internal and external elastic laminae.

Invariably the subclavian artery was an elastic artery with a media consisting of 30 to 40 elastic lamellae (Fig 2A). In all individuals we observed a varying histological pattern from the proximal IMA to the distal segments of the MPA and the SEA. At the origin of the IMA, in its proximal 1 cm, being a transitional area between the subclavian artery and the IMA, the media invariably was elastic, containing 8 to 18 (mean, 10) elastic lamellae, including the internal and external elastic laminae (Fig 2B). Because of the extremely variable cross-sectional luminal area and intimal thickness in this segment of the IMA it was not further involved in the histological and quantitative analysis. In only 2 individuals, who were 51 and 67 years of age, the media of the IMA was elastic along its entire length, with a number of elastic lamellae that varied from 8 to 12 (mean, 10). In the other 9 individuals we observed an alternating elastomuscular-elastic histological pattern in the IMA: the first 20% to 30% of the total length of the IMA was generally elastomuscular (Fig 2C). In this segment the smooth muscle content in the media prevailed over a number of 5 to 7 (mean, 6)

Fig 2. Documentation of the varying histological pattern of the internal mammary artery (IMA) along its downstream course in a 56-year-old man: (A) Subclavian artery in direct proximity to the origin of the IMA, its media containing 30 to 40 elastic lamellae; (B) The origin of the IMA with a mean number of 10 elastic lamellae in its media; (C) Proximal segment of the IMA with an elastomuscular media, containing a mean number of 5 elastic lamellae; (D) Mid segment of the IMA with an almost purely elastic media containing a mean number of 9 elastic lamellae; (E) Distal segment of the IMA with a predominantly muscular media and a limited number of elastic lamellae; (F) Proximal 1 cm of musculophrenic artery with rare elastic lamellae in a predominantly muscular media; (G) Distal musculophrenic artery with a muscular media containing rare elastic fibers; (H) Proximal 1 cm of superior epigastric artery with few incomplete elastic lamellae in a predominantly muscular media; (I) Distal superior epigastric artery with a muscular media containing rare elastic fibers. (Elastin-trichrome after Masson stain; A: $\times 80$, B to H: $\times 140$, both before 25% reduction.)

elastic lamellae (Figs 3, 4). More downstream in these IMAs we observed a rather abrupt transition into an elastic pattern, which continued up to 70% to 80% of the total length of the IMA. This elastic segment was composed of 8 to 12 (mean, 9) elastic lamellae (Figs 2D, 4, 5). In all 9 individuals we observed a second elastomuscular segment with 5 to 7 (mean, 6) elastic lamellae, analogous to the proximal one, starting at 70% to 80% of the total length of the IMA. In 5 of these 9 individuals this distal elastomuscular segment extended up to the epigastric bifurcation, but in the remaining 4 it abruptly (at 80% to 90% of the total length of the IMA) converted into a muscular one with rare (mean, 3) elastic lamellae (Figs 2E, 3). In all 11 individuals the elastic, elastomuscular, or muscular (with rare elastic lamellae) patterns continued as an elastomuscular or mainly muscular pattern in the media of the first 1 to 2 cm of the MPA, with a mean number of elastic lamellae of 5 and 3, respectively (Figs 2F, 6). In all individuals in the proximal 1 to 2 cm of the SEA only the muscular pattern, primarily without or with incomplete elastic lamellae, was seen (Figs 2H, 7, 8). More distal in the MPA and SEA the media consisted almost purely of smooth muscle cells, with elastic fibers scarcely dispersed in between and without any elastic lamellae (Figs 2G, 2I).

The mean number of discontinuities in the circumfer-

Fig 3. Distribution of the various histological patterns in the media of 11 internal mammary artery specimens. Note the interindividual variability in histological pattern of the media at the various locations. In a minority of patients the media of the distal segment of the internal mammary artery was muscular with rare elastic lamellae. (1 = elastic media; 2 = elastomuscular media; 3 = muscular media with rare elastic lamellae; 4 = muscular media without elastic lamellae.)

Fig 4. Distribution of the mean number of elastic lamellae in the media of the internal mammary artery along its downstream course.

ential internal elastic lamina of the elastic and elastomuscular segments of the IMA was 18 ± 10 and 35 ± 12 , respectively (mean $\pm$ standard deviation). For the proximal segments of the MPA and the SEA with a muscular media with rare elastic lamellae these numbers were 37 ± 15 and 41 ± 17 , respectively. For the distal segments of the MPA and SEA with a muscular media without elastic lamellae these numbers were 89 ± 31 and 92 ± 39 , respectively. The number of discontinuities in the internal elastic lamina was significantly different among the elastic, elastomuscular, and muscular segments without elastic lamellae (elastic versus elastomuscular, $p = 0.01$; elastic versus muscular without elastic lamellae, $p = 0.001$; elastomuscular versus muscular without elastic lamellae, $p = 0.002$). The number of discontinuities in the internal elastic lamina was not significantly different between the elastomuscular and the muscular segments with rare elastic lamellae. Especially in muscular segments with a great number of discontinuities in the internal elastic lamina we frequently observed single or multiple layers of reduplicated internal elastic lamina, which were present as thin sealing layers on the luminal aspect of the defective internal elastic lamina (Fig 9).

Quantitative Results

The mean cross-sectional luminal area of the proximal elastomuscular and elastic segments of the IMA (both 1.9 mm^2) was significantly greater than that of the distal elastomuscular segment of the IMA (1.2 mm^2) and that of the muscular segments of the MPA (0.9 mm^2) and SEA (0.7 mm^2) ($p < 0.01$). The mean cross-sectional luminal area of the distal elastomuscular segment of the IMA (1.2 mm^2) was significantly greater than that of the distal, purely muscular segments of the MPA (0.9 mm^2) and SEA (0.7 mm^2) ($p < 0.01$), whereas that of the latter two did not differ significantly from that of the proximal segments of

the MPA and SEA with a muscular media with rare elastic lamellae (1.0 mm^2 and 0.8 mm^2 , respectively). Although the cross-sectional luminal area of the IMA along its downstream course gradually decreased, this decrease reached statistical significance only beyond the 90% segment. The small luminal diameter of the IMA, MPA, and SEA in our study is mainly due to rigor mortis and cross-linking contracture of the vessel wall, caused by fixation in 4% formaldehyde solution.

In the 30% to 70% segment of the IMA the number of elastic lamellae (mean, 9) did not vary significantly at the various levels. Obviously, in this primarily elastic segment the number of elastic lamellae was significantly greater than that in the proximal and distal elastomuscular segments of the IMA (mean, 6) ($p < 0.01$) (see Fig 4). The density of the elastic lamellae along the downstream course of the IMA showed a similar pattern (Fig 10).

The absence of elastic lamellae in the media had a profound effect on the degree of intimal hyperplasia: the intima was significantly thicker in the purely muscular

Fig 5. Detail of elastic media at mid level of the internal mammary artery. Note the intact internal elastic lamina (arrows), the absence of intimal thickening, and the moderate presence of smooth muscle cells between the elastic lamellae. The intima consists of a thin layer of endothelial cells, which in this section, due to fixation artifact, is not attached to the internal elastic lamina. (Elastin-trichrome after Masson stain; $\times 400$ before 3% reduction.)

Fig 6. Distribution of the various histological patterns in the media of the musculophrenic artery along its downstream course. varied along the downstream course of the IMA (being slightly greater in the proximal and distal elastomuscular segments than in the elastic segments), but these differences were not significant.

Comment

In the present study and in another study [5] we observed a correlation between the absence of elastic lamellae in the media and an increased number of discontinuities in the internal elastic lamina, and, as a potential result of this, increased intimal thickening. In the purely muscular segments of the MPA and SEA the intima was significantly thicker than the intima in the more proximal segments of these arteries (muscular with rare elastic lamellae) and the intima in the IMA (elastic or elastomuscular). Although one may argue that these findings may

Fig 9. Discrepancy in degree of intimal thickening between mid-segment internal mammary artery (A) and a specimen of a muscular segment of the musculophrenic artery (B), as seen in a considerable number of specimens. (A) Note the multiple elastic lamellae in the media, the relatively intact internal elastic lamina, and the thin intima. (B) In contrast, note the multiple discontinuities in the internal elastic lamina (arrows), the abundant presence of smooth muscle cells in the thickened intima, and the formation of multiple layers of reduplicated internal elastic lamina in the intima. (Elastin-trichrome after Masson stain; $\times 140$ before 30% reduction.)

be coincidentally related but not causally, similar findings are reported in a comparative histological study between the muscular coronary artery and the primarily elastic IMA by Sims and Gavin [6], in which the number of discontinuities in the internal elastic lamina and the degree of intimal thickening were significantly greater in the former vessel. Based on their and our observations we conclude that elastic lamellae in the media may protect against the occurrence of discontinuities in the internal elastic lamina and, secondarily, against intimal thickening,

Fig 10. Distribution of the mean density of elastic lamellae (expressed per square micrometer) in the media of the internal mammary artery along its downstream course. Note that the density is highest in the 20% to 70% segment of the internal mammary artery, which is in concordance with the high number of elastic lamellae in this segment (see Fig 4).

ing, even if the number of lamellae is small. The study by Sims and Gavin [6] also suggests that gaps in the internal elastic lamina allow smooth muscle cells of the media to proliferate into the intima and that the rate of this growth reflects the response of medial smooth muscle cells to tension on the arterial wall. Other studies by Sims [7, 8] confirm the structural importance of the internal elastic lamina and its relationship to intimal thickening. Recent research in vascular pathology has shown that medial smooth muscle cells are mesenchymal cells capable of changing from a contractile to a synthetic type in response to damage of the internal elastic lamina and increasing tangential tension on the vessel wall [9]. This process leads to active cell division and synthesis of collagen, elastin, and proteoglycan matrix [10, 11]. The occurrence of discontinuities in the internal elastic lamina enables penetration of proliferating smooth muscle cells from the media into the intima. Within the intima, the proliferating smooth muscle cells produce elastin, often as a coherent reduplicated internal elastic lamina, which can be seen as single or multiple thin sealing layers on the luminal aspect of the defective internal elastic lamina. This phenomenon was frequently observed in our specimens, especially in the MPA and SEA with a purely muscular media. Almost invariably such repair is imperfect, and with the passage of time, breakdown of the reduplicated internal elastic lamina occurs, leading to serious impairment of attachment of endothelial cells, cell loss, and the development of bare areas. Such bare areas may enhance the infiltration of macromolecules of all sizes, including lipoproteins, and cells of the circulating blood, thus accelerating the development of atherosclerotic lesions [12, 13].

Due to the effect of pulsatile stress on the proliferation of smooth muscle cells from the media into the intima the rate of intimal thickening may be enhanced in the central aorta and its branches in comparison with the IMA, in

which the hemodynamics are less vigorous [14, 15]. Such proliferative smooth muscle cell response has been observed in systemic and pulmonary hypertension and in the culture of medial cells from hypertensive animals and from experimental atherosclerosis [16-19]. In our study the degree of intimal thickening was substantially greater in the subclavian artery and the first centimeter of the IMA than in the remainder of the IMA, although this effect was not quantified because it was not the subject of our study. Although no other factor than their intrinsic growth potential would appear necessary to explain the growth of medial smooth muscle cells through defects in the internal elastic lamina to populate the intima, other factors may enhance this rate of growth, and once it has begun, continued increase of intimal thickness throughout life would appear inevitable.

The findings as presented in this study may have implications with regard to selection of the anastomotic site in the IMA. We observed a considerable interindividual variability with regard to the extent of a primarily elastic media in the IMA. In 7 patients the distal segment of the IMA was either elastic or elastomuscular, whereas in 4 patients the distal 10% to 20% segment of the IMA was muscular with rare elastic lamellae. These findings suggest that, based on the assumption that use of an elastic or elastomuscular conduit is superior to use of a primarily muscular one in myocardial revascularization, it may be beneficial not to use the distal 10% to 20% segment of the IMA. This strategy has the additional advantage that the IMA cross-sectional luminal diameter proximal to or at the 80% to 90% level may better match the diameter of the coronary artery than the more distal segment. Selection of the anastomotic site in the MPA or the SEA is not encouraged because of the potentially increased risk of intimal thickening and the significantly smaller luminal diameter of these vessels.

To expand the benefits of the elastic and elastomuscular IMA the shortest possible route to the heart should be established [20-23]. For the same reasons bilateral and sequential grafting with the IMA is beneficial [2-4]. To gain additional length of the IMA transection of the pleura and fascia beneath the IMA may be a valuable technique [24]. However, we do not favor complete or partial skeletonization of the IMA, as advocated by Sauvage and associates [2] and Keeley [25], respectively, because this technique has an increased risk of iatrogenic disruption of the internal elastic lamina, which may be especially deleterious in segments with a high muscular content because it may provoke enhanced intimal thickening [26]. A reported patency rate of free, pedicled IMA grafts approximating that of in situ IMA grafts [27] is consistent with our supposition that the intima and media of the nondiseased IMA are nourished entirely from the lumen [1]. Therefore, any discrepancy in patency rate between in situ and free IMA grafts may be attributable primarily to the proximal anastomosis.

Because of absence of the protective effect of elastic layers in the media on the development of discontinuities in the internal elastic lamina, muscular arterial conduits such as the gastroepiploic artery and the inferior epigas-

tric artery, in analogy to the MPA and SEA, are likely to be more prone to enhanced intimal thickening than elastic and elastomuscular conduits. This hypothesis is supported by one of our previous studies [28] and a study by Suma and Takanashi [29], in which intimal thickening in the right gastroepiploic artery in its natural environment, especially in its proximal segment, was more pronounced than in the IMA. On the other hand, a recent histological study of the inferior epigastric artery in its natural environment suggested a relatively low degree of intimal hyperplasia [30]. Exposure of muscular arterial conduits to the high pressure demands of the ascending aorta, however, may lead to an enhanced rate of intimal thickening, which may prove adaptive to their new environment but also may adversely influence their long-term patency rates. Clinical evidence of accelerated intimal thickening of muscular conduits in myocardial revascularization has been provided by reports of a high occlusion rate of radial artery grafts [31]. Therefore, long-term patency curves of the currently used muscular conduits (mainly the right gastroepiploic and inferior epigastric arteries) must be established before their widespread use in myocardial revascularization can be confidently advised.

Finally, the present study allows some remarks about the vasoregulatory function of the IMA. Although the IMA primarily functions as a pressure reservoir by virtue of the elastic properties of its wall, the elastomuscular and muscular segments of the IMA, MPA, and SEA may have important flow-regulatory functions with regard to perfusion of the anterior chest wall, the mammary gland, the diaphragm, and the rectus abdominis muscle. As such, the muscular and elastomuscular segments of the IMA may be primarily responsible for the wide spectrum of physiologic adaptability of the IMA conduit, vasospasm as observed in low-flow state and enlargement of the IMA in time to meet the high metabolic myocardial demand being the ends of this spectrum [32-34].

Platelet Protection by Low-Dose Aprotinin in Cardiopulmonary Bypass: Electron Microscopic Study

Jacob Lavee, MD, Zvi Raviv, MD, Aram Smolinsky, MD, Naphtali Savion, PhD, David Varon, MD, Daniel A. Goor, MD, and Rephael Mohr, MD

Department of Cardiac Surgery, The Maurice and Gabriela Goldschleger Eye Institute, and The National Hemophilia Center, The Chaim Sheba Medical Center, and The Sackler Faculty of Medicine, Tel Aviv University, Tel Hashomer, Israel.

To evaluate the effect of low-dose aprotinin during cardiopulmonary bypass on platelet function and clinical hemostasis, 30 patients undergoing various cardiopulmonary bypass procedures employing bubble oxygenators were randomized to receive either low-dose aprotinin (2×10^6 KIU in the cardiopulmonary bypass priming solution, 15 patients [group A]) or placebo (15 patients [group B]). Blood samples were collected before and after cardiopulmonary bypass to assess platelet count and aggregation on extracellular matrix, which was studied by a scanning electron microscope. On a scale of 1 to 4 preoperative mean platelet aggregation grades were similar in both groups (3.8 ± 0.5 and 3.5 ± 0.5 for groups A and B, respectively). Postoperatively, platelet aggregation on extracellular matrix decreased slightly in group A

(2.8 ± 1.3 ; $p < 0.01$) and significantly in group B (1.3 ± 0.5 ; $p < 0.001$). Eleven of the 15 patients in group A remained in aggregation grade 3 or 4 compared with none of the group B patients. Platelet count was similar in both groups preoperatively and postoperatively. Total 24-hour postoperative bleeding and blood requirement were lower in the aprotinin group (487 ± 121 mL and 2.3 ± 1.0 units) than in the placebo group (752 ± 404 mL and 6.8 ± 5.1 units; $p < 0.01$). These results show that the use of low-dose aprotinin during cardiopulmonary bypass provides improved postoperative hemostasis, which might be related to the protection of the platelet aggregating capacity.

(*Ann Thorac Surg* 1993;55:114-9)

One of the major causes of bleeding after cardiac operations using cardiopulmonary bypass (CPB) is platelet dysfunction [1, 2]. This problem could be overcome by transfusing the patients with fresh whole blood postoperatively [3, 4]. However, in recent years, the use of the protease inhibitor aprotinin during CPB has emerged as a promising prophylactic measure in reducing postoperative bleeding and blood transfusion requirements [5-15]. This clinical effect has been shown [7, 15] to be mediated by preservation of the platelet function.

Most studies reporting the use of aprotinin have used the high-dose regimen, whereby the patient would receive a total of 6 to 7×10^6 KIU aprotinin, starting with a loading dose before sternotomy and continuing during operation. Recently, several studies [7, 16, 17] have reported using the low-dose regimen, whereby only 2×10^6 KIU aprotinin is added to the priming volume of the oxygenator, with good clinical results.

The aim of the present study was to evaluate the clinical effect of using aprotinin in the low-dose regimen employing bubble oxygenators, and to correlate this effect to platelet function. We evaluated platelet function by using the extracellular matrix (ECM) that simulates the in vivo adhesion and aggregation of platelets on the subendothe-

lium [18]. The extracellular matrix is produced by cultured bovine corneal endothelial cells and closely resembles the human vascular subendothelial basal lamina in origin and chemical composition [18]. The ECM has served as an in vitro model in the study of platelet-subendothelial interaction [4, 18-21]. The incubation of human platelets on ECM induces platelet adhesion, aggregation, thromboxane A_2 formation, and a release reaction [18-21]. In the present study, platelet aggregation on ECM was studied with the scanning electron microscope.

Patients and Methods

Thirty patients undergoing various CPB procedures (Table 1) were randomized to receive either low-dose aprotinin (study group [group A], 15 patients) or placebo (control group [group B], 15 patients). The study group received 2×10^6 KIU aprotinin (Trasylol; Bayer, Leverkusen, Germany) added to the priming volume of the oxygenator. No additional aprotinin doses were given to the patients. Each patient in the control group (group B) received equivalent volumes of placebo solution (saline solution 0.9%) added to the priming volume of the oxygenator.

The mean age of the patients was 61 ± 9 years (range, 40 to 78 years), with no difference between the two groups (see Table 1). No patient had been receiving dipyridamole or aspirin-containing drugs during the 4 weeks preceding

Accepted for publication April 27, 1992.

Table 1. Clinical and Operative Data

Variable	Group A: Aprotinin (n = 15)	Group B: Placebo (n = 15)
Age (y)	62 ± 11	60 ± 9
Sex (M/F)	13/2	11/4
Bypass time (min)	145 ± 42	130 ± 48
Aortic cross-clamp time (min)	52 ± 35	40 ± 24
Lowest body temperature (°C)	27 ± 4.8	27 ± 3.7
Procedure		
CABG	9	12
Redo CABG	3	2
Valve replacement	1	1
CABG + valve replacement	2	...

CABG = coronary artery bypass grafting.

the operation. For all patients a Sarns pump (Sarns Inc, Ann Arbor, MI) and bubble oxygenator (Bentley Laboratories, Inc, Irvine, CA) were used. The oxygenators were primed with 1,500 mL of Hartmann's solution and 500 mL of dextrose 5% solution.

The two groups were similar regarding bypass time, aortic cross-clamping time, and lowest body temperature (see Table 1). All patients were rewarmed to 35°C before discontinuation of CPB. Reversal of the heparin effect by protamine was monitored by the activated clotting time.

All pump blood was returned to the patient through the aortic cannula or intravenously by infusion bags without hemoconcentration. None of the patients had to be returned to the operating room because of excessive mediastinal bleeding.

Blood samples from each patient, obtained through a flushed arterial catheter, were collected before and at termination of CPB to assess platelet count and aggregation. Platelet count was measured with a Coulter-Counter-S-Plus II (Luton, England).

Platelet aggregation was evaluated by the ECM model, using a scanning electron microscope [4, 22].

Preparation of Dishes Coated With Extracellular Matrix

Corneal endothelial cells were grown on 24-well-type culture plates (Nunc GmbH, Roskilde, Denmark) with 5% dextran T-40 (Pharmacia, Fine Chemicals, Sweden) added to the growth medium [18, 20, 21]. Cultures were washed once with phosphate-buffered saline (PBS) and exposed to 0.5% Triton-X 100 solution in PBS (volume per volume) followed by exposure to ammonium hydroxide solution, 0.1 mol/L, and washing in PBS. Extracellular matrix-coated dishes containing PBS were stored before use at 4°C for periods up to 3 months.

Platelet Reactivity With Extracellular Matrix

Whole blood, 0.5 mL, in a citrate buffer from each sample was added to the tissue culture well coated with ECM

Fig 1. Scanning electron micrographs of the four aggregation grades on extracellular matrix: (a) grade 1; (b) grade 2; (c) grade 3; (d) grade 4. See text for details. (×8,000.)

(16-mm diameter) and shaken (Orbit Shaker, Lab-Line Instruments, Melrose Park, IL; 100 rpm) for 30 minutes at room temperature. At the end of the incubation period, all the blood from the culture dish was collected and the dish was gently flushed several times with PBS.

Preparation for Study With Scanning Electron Microscope

The ECM-coated dishes, now containing platelet aggregates, were fixed by 2.5% phosphate-buffered glutaraldehyde (pH 7.2), then washed in the same buffer and postfixed by osmium tetroxide 2%. The third fixation was by a solution of 2% tannic acid-guanidine hydrochloride. The triple-fixed samples were dehydrated in graded alcohol solutions, and thereafter the alcohol was exchanged to Freon 112 by graded Freon solutions (Du Pont Company, Wilmington, DE). The samples were air-dried, gold-coated, and examined by a Jeol 840 scanning electron microscope (Jeol USA Inc, Peabody, MA).

Grading Platelet Aggregates on Extracellular Matrix

As a method of quantitating the aggregation of platelets on ECM as seen by the scanning electron microscope, four distinct aggregation grades were defined according to the

various platelet morphologic types previously described [23] (Fig 1).

In grade 1 (see Fig 1a), the platelets are discoid with lentiform appearance, have a smooth surface, and lack any pseudopodia. In this grade the platelets do not adhere to each other, and each platelet can be seen individually.

In grade 2 (see Fig 1b), the platelets display the first signs of activation, and they appear with slender dentrite-like pseudopodia, still separated from each other.

In grade 3 (see Fig 1c), the aggregation process is more advanced: The platelet body spreads, showing multiple dentritic pseudopodia, and the platelets start to cluster. In this immature aggregate, each platelet can still be identified separately.

Grade 4 (see Fig 1d) consists of a mature aggregate in which large clumps of platelets are seen and in which individual platelets are difficult to define.

In each sample, 40 scanning electron microscopic fields containing platelets were examined at a magnification of 8,000, each given an individual grade. The final aggregation grade of each sample was derived by calculating the arithmetic mean of the individual grades. Although aggregates of different grades could be found in any given sample, a dominant grade for each sample could always be identified. To avoid any element of subjectivity in the grading process, the observers assigned grades "blindly," that is, they were not aware of the group to which each sample belonged while grading it.

Blood Transfusion Policy

The policy of blood transfusion in the intensive care unit differed in the immediate and late postoperative periods. Most blood transfusions were given in the first 8 postoperative hours. The indications for blood transfusion were hemodynamic parameters, such as low systemic and left atrial pressures, and constricted periphery. The amount transfused depended strongly on the amount of blood lost through the chest tubes. Once the patient's condition had stabilized completely, the indication for further blood transfusion was a hemoglobin level less than 10 g/100 mL. Platelet concentrate transfusions were administered only to patients with active bleeding if platelet count was less than $100 \times 10^9/L$.

Blood loss from the chest tubes, the number of blood

Fig 3. Changes in individual platelet aggregation (PLT Agg) grades in the two groups from before operation to after cardiopulmonary bypass (CPB). Numbers indicate number of patients.

Fig 4. Scanning electron micrographs of a patient from the aprotinin group: (a) preoperative (grade 4); (b) after cardiopulmonary bypass (grade 4). ($\times 8,000$.)

units required, and the total number of blood products transfused (red blood cells, plasma, and platelet units) in the initial 24 hours after the patient arrived at the intensive care unit were recorded for evaluation of clinical hemostasis.

Statistical Analysis

Results were expressed as mean $\pm$ standard deviation. Paired and nonpaired *t* tests were used for parametric variables, and Fisher's exact test and the Mann-Whitney test for nonparametric variables.

Results

Preoperative platelet count in group A (aprotinin group; $172 \pm 44 \times 10^9/L$) did not differ significantly from that in group B ($152 \pm 50 \times 10^9/L$). Similarly, both groups showed significantly lower platelet count after CPB (97 ± 23 and $88 \pm 30 \times 10^9/L$ for groups A and B, respectively; $p < 0.001$), with no significant difference between the two groups.

The mean grade of platelet aggregation on ECM before CPB was similar in both groups (3.8 ± 0.5 and 3.5 ± 0.5 for groups A and B, respectively; $p =$ not significant) (Fig 2). Postoperatively, mean platelet aggregation grade on

ECM was slightly decreased in group A (2.8 ± 1.3 ; $p < 0.01$) and significantly decreased in group B (1.2 ± 0.5 ; $p < 0.001$) (see Fig 2). Eleven of the 15 patients in group A remained in grades 3 or 4, and only 4 could not form aggregates on ECM (grades 1 or 2) (Fig 3). Conversely, all patients in the control group (group B) showed significant decrease of their postoperative aggregation grades to grades 1 or 2, and none showed normal aggregation (see Fig 3). Scanning electron micrographs of patients from each group are shown in Figures 4 and 5.

Total 24-hour blood loss in group A was significantly lower than in group B (Table 2). Patients in the aprotinin group received fewer homologous red blood cell units. Only 1 patient in this group received platelet transfusion, and this accounted for the extremely low exposure to homologous blood products (see Table 2).

Comment

The protease inhibitor aprotinin has been shown in recently published studies to be a promising prophylactic agent in managing CPB-related bleeding [5-14]. We [15] and others [5-14] have shown that when given in a high dose, namely, before and during the entire procedure, aprotinin has the capacity to reduce postoperative blood

Fig 5. Scanning electron micrographs of a patient from the placebo group: (a) preoperative (grade 4); (b) after cardiopulmonary bypass (grade 1). ($\times 8,000$.)

Table 2. Postoperative Bleeding and Blood Requirement

Variable	Group A (Aprotinin)	Group B (Placebo)	p Value
24-hour bleeding (mL)	487 ± 121	752 ± 404	0.05
RBC (U)	2.1 ± 1.1	3.6 ± 1.8	0.01
Total blood products (U)	2.3 ± 1.0	6.8 ± 5.1	0.01

RBC = red blood cells; Total blood products = RBC + plasma + platelets.

loss and blood transfusion requirement by preserving the platelets' adhesive and aggregatory functions.

As the high-dose regimen was devised on theoretical grounds [14, 24], few attempts have been reported [7, 16, 17] using a low-dose regimen, namely, 2×10^6 KIU aprotinin in the priming solution of the oxygenator. In our study we used the low-dose regimen and demonstrated clinical beneficial results in terms of reduced postoperative bleeding and blood transfusion similar to those observed by previous groups who reported the use of the low-dose regimen [7, 16, 17].

Moreover, using the ECM model we have shown that the improved clinical hemostasis observed with the low-dose aprotinin regimen may be attributed to the partially preserved platelet aggregatory capacity. Seven of the 15 patients who received low-dose aprotinin maintained normal platelet aggregation (grade 4) after CPB, and another 4 displayed near-normal aggregation (grade 3), as opposed to none of the placebo group patients, who all displayed deranged aggregation (grades 1 and 2). Similar results, albeit somewhat better, were shown by us when the high-dose aprotinin regimen was tested [15]. In that group all patients maintained normal or near-normal platelet aggregation after CPB.

Previous reports [7, 25] have correlated the improved hemostasis provided by aprotinin to the preservation of the platelet glycoprotein Ib-dependent adhesive capacity. By using the ECM model as an in vitro model for the study of platelet subendothelium interaction [18-21], we have demonstrated an additional effect of CPB on platelets represented by the deranged aggregatory capacity found in all patients in the placebo group, who showed some platelet adhesion to the ECM (grades 1 and 2), but no signs of aggregation. The lack of aggregation on ECM in the placebo group might be due to fibrinogen receptor defect, as Glanzman's thrombasthenic platelets (which are deficient of glycoprotein IIb/IIIa) exhibit the same response to ECM [19]. These results concur with those of Rinder and colleagues [26, 27], who have shown selective decreases in platelet glycoprotein IIb/IIIa, in addition to Ib, as a result of CPB. The assumption that other agonists present in the ECM, such as collagen or fibronectin, might be responsible for the improved aggregation found in those patients who received aprotinin is negated by the fact that those agonists did not play any role in the placebo group.

It should be noted that the discrepancy in the mode of action of aprotinin between our observation and that of others [7, 25] may be explained at least partially by the use

of bubble oxygenators in our study and membrane oxygenators by the others. It is known that platelet aggregation is better preserved by membrane than by bubble oxygenators [28].

As platelet aggregation on ECM requires both fibrinogen [19] and von Willebrand's factor [29] as ligands for the activated glycoprotein IIb/IIIa, our model is not sensitive enough to differentiate which domain on the glycoprotein IIb/IIIa was protected by aprotinin. The preserved aggregatory capacity of platelets in the aprotinin group of our study suggests that at least part, if not all, of the glycoprotein IIb/IIIa was protected.

A possible explanation for the protective effect of aprotinin on blood loss during CPB has recently been suggested [14, 30]. According to this hypothesis, plasmin, generated during CPB, activates the platelets and causes changes in the distribution of glycoproteins IIb/IIIa and Ib on the platelet's membrane [31]. This effect is further enhanced by the lower temperatures used for the CPB procedure [32]. Activated platelets might become nonreactive or cleared from the blood by interaction with components of the CPB system, and thus bleeding tendency is increased. Aprotinin, by its known antifibrinolytic effect [33, 34], may protect postoperative platelet aggregation by inhibiting the high deleterious plasmin level [33]. Our study has not addressed the antifibrinolytic effects of aprotinin but has shown that the final pathway, namely, platelet aggregatory capacity, is preserved by the drug.

We conclude that the use of low-dose aprotinin during CPB, using bubble oxygenators, provides improved postoperative hemostasis by preserving the platelet aggregatory capacity. These beneficial effects of aprotinin have reconfirmed the utmost importance of platelets in postoperative hemostasis.

We greatly appreciate the technical expertise and assistance of Jacob Langsam, MSc, the Electron Microscopy Unit, Life Sciences Department, Bar Ilan University, and of Mr Henry Fridman, Chief Perfusionist at the Sheba Medical Center, Tel Hashomer, Israel.

Bovine Internal Mammary Artery as a Conduit for Coronary Revascularization: Long-Term Results

Ian M. Mitchell, FRCS, A. Rashid Essop, MRCP, Peter J. Scott, MRCP, Paul G. Martin, BSc, Nirmal K. Gupta, MCh, Nigel R. Saunders, FRCS, R. Unnikrishnan Nair, FRCS, and Gordon J. Williams, FRCP

Departments of Cardiac Surgery and Cardiology, Killingbeck Hospital, Leeds, England

Graft patency after coronary artery bypass grafting depends largely on the choice of conduit. Because an increasing number of patients have insufficient or poor-quality autologous material, there is a need for a suitable synthetic graft that is readily available and easy to handle and that has good long-term patency. Early results suggest that the bovine internal mammary artery graft may meet these criteria. We have used a total of 26 such grafts in 18 patients. Postoperative angiography has been performed in 19 grafts in 14 patients, 3 to 23 months after operation; of these grafts, 3 are currently patent

(15.8%, compared with 85.7% and 75.0% patency for native internal mammary artery and saphenous vein grafts in the same patients). We report the results of clotting studies and an analysis of lipid status. These patients do not, however, appear to represent any atypical group, either in terms of coagulopathy, native coronary artery size, or the type of vessel disease. Nevertheless, our poor results contrast markedly with the early enthusiasm reported from other centers.

(*Ann Thorac Surg* 1993;55:120-2)

During the last decade many countries have witnessed a dramatic increase in the number of patients undergoing coronary artery bypass grafting. As a consequence, the number with insufficient or inadequate autologous vessels suitable for use as coronary artery grafts is also increasing. These patients may include those who have had previous heart operations and those with bilateral varicose veins, either with or without a previous history of surgical intervention such as sclerotherapy or vein stripping.

A successful outcome after coronary artery bypass grafting does, however, depend very much on the choice of graft conduit. Saphenous vein is still the most commonly used material with 45% to 50% of conduits remaining patent at 7 years [1, 2]. More recently, however, the internal mammary artery has been used and has been shown to have even better long-term patency with approximately 94% of grafts still functioning over the same time span [1-3]. Bilateral internal mammary artery grafts [4] and right gastroepiploic artery grafts [5] are similarly successful.

Many other natural and synthetic graft materials have been used, but unlike the conduits described above, none have achieved comparable success. These materials include arm veins (20% patency at 5 years) [6], umbilical veins, and polytetrafluoroethylene grafts [7, 8].

Recently, bovine internal mammary arteries have become commercially available (Bioflow; Bio-Vascular Inc, Saint Paul, MN). Initial experience using these for coronary artery bypass suggests early patency rates of 85% at

6 months [9]. This study addresses the question of long-term patency.

Material and Methods

In the 2-year period between January 1990 and December 1991, 26 bovine internal mammary artery grafts (Bioflow; Somatech, Oxford, UK) were implanted into 18 patients. In each case, previous operation or saphenous varicosity limited the availability of autologous graft material and consent was therefore obtained for heterologous conduits to be used. There were 13 men and 5 women, with a mean age of 61 years (range, 52 to 71 years). Two patients had had previous coronary artery operations, and 1 of these and 3 others underwent concurrent mitral or aortic valve replacement or repair. Two were insulin-dependent diabetics.

In each case cardiopulmonary bypass and suture techniques followed a standard pattern, distal anastomoses being carried out with continuous 6-0 Prolene (Ethicon, Edinburgh, UK) and proximal anastomoses with continuous 5-0 Prolene; 4 mm conduits were used in 2 patients and 3 mm in the remainder. Endarterectomy was required in 6. Details of the vessels grafted with bovine internal mammary arteries are listed in Table 1. In this group of patients, however, a total of 21 other vessels were also grafted, using native internal mammary arteries in 10, autologous saphenous vein in 10, and the inferior epigastric artery in 1. Where the native left internal mammary artery was available, it was used to graft the left anterior descending artery. When saphenous vein was the only native conduit available, it was used to graft the most important vessel based on the particular angiographic findings.

Accepted for publication April 30, 1992.

Table 1. Bovine Internal Mammary Artery Graft Positions in 18 Patients

Vessel	No. of Grafts	Vessel size (mm)		No. With Distal Disease
		Range	Mean	
LAD	8	1.0-2.5	1.75	2
Circ	5	2.0-3.0	2.25	0
RCA	13	1.0-3.5	2.00	5

Circ = circumflex artery or its branches; LAD = left anterior descending artery; RCA = right coronary artery or posterior descending artery.

After operation, four anticoagulant policies were used. Three patients received only aspirin (75 mg daily), 8 received only warfarin, 4 received both aspirin and warfarin, and 3 received warfarin and dipyridamole.

Two patients died, 1 at 10 months because of cardiac failure and the other at 4 months, following myocardial infarction. Two patients have been readmitted to a hospital with severe angina on more than one occasion; each has recently had a large myocardial infarction and both refused restudy. With informed consent, however, the remaining 14 patients were admitted for reinvestigation at a mean of 9.5 months after operation (range, 3 to 23 months). After clinical assessment, each patient underwent angiography; 6F catheters were inserted by a femoral approach and each native vessel and graft (prosthetic and autologous) was selectively restudied. Digital subtraction angiography was also performed whenever selective exploration of the ascending aorta had failed to reveal all the expected grafts. In addition to angiography, blood was collected for measurement of the following parameters: urea and electrolyte concentrations, liver function tests, low-density and high-density lipoprotein cholesterol concentrations, lipid profiles, plasma viscosity, fibrinogen concentrations, platelet function tests, and a clotting screen.

Results

In 18 patients receiving bovine internal mammary artery grafts, 13 complained of recurrent angina. This was mild in 5, but myocardial infarction occurred in 4.

Of the 19 bovine internal mammary grafts restudied, only 3 were patent (15.8%). The results are summarized in Table 2 and compare with patency rates of 85.7% for native internal mammary arteries and 75.0% for saphenous veins.

Three patients had acute episodes of chest pain requiring hospital admission shortly before they were restudied;

Table 2. Patency Rates in 14 Patients Restudied 3 to 23 Months After Operation

Graft Type	No. of Grafts	No. Patent	Patency Rate
Bovine IMA	19	3	15.8%
Native IMA	7	6	85.7%
Vein	8	6	75.0%
Epigastric artery	1	0	0%

IMA = internal mammary artery.

in 1, myocardial infarction had occurred. The grafts were blocked in all 3 patients, raising the possibility of occlusion being an acute event. Severe chest pain developed in 1 further patient on the tenth postoperative day; emergency angiography revealed a patent bovine internal mammary graft, but early intraluminal irregularity. Restudy at 6 months showed total occlusion.

There were no abnormalities in the lipid or cholesterol profiles, electrolytes, liver function tests, or fibrinogen concentrations. Each patient taking warfarin was found to be adequately anticoagulated; only 4 of 7 patients taking aspirin, however, had reduced platelet aggregation in response to arachidonic acid stimulation. Anticoagulant policy did not appear to affect the patency rate of bovine internal mammary grafts in this series.

Comment

The ideal artificial graft for coronary artery bypass should be of small diameter, freely available (and in different sizes), inert, pliable and easy to use, and associated with good long-term patency. Bioflow bovine internal mammary artery grafts are harvested from cows, treated with dialdehyde, and sterilized with ethanol and propylene oxide. They are therefore inert and freely available, so meeting two of the criteria for an ideal artificial conduit.

Early laboratory work in dogs suggested that bovine internal mammary artery grafts had a lower thrombogenicity than polytetrafluoroethylene grafts at 3 months [10] and were suitable for coronary artery bypass. Clinical use was first reported in 1988 [11], and although subsequent studies support the use of these grafts, only one has actually restudied graft patency [9]. In this, 11 of 13 bovine internal mammary artery grafts (85%) were patent at 6 months, but there is no mention of anticoagulant policy. Our report of "long-term" bovine internal mammary artery graft patency is in complete contrast to these results from elsewhere, as we have found only 15.8% patency in 19 grafts restudied 3 to 23 months after implantation.

Reinvestigation of native internal mammary artery and saphenous vein graft patency in the same patients, is by comparison, consistent with results from other centers [1, 2]. Because the same suture techniques were used for all types of graft, because these compare with techniques reported elsewhere [12], and because more than one surgeon implanted our grafts, it is unlikely that surgical method is to blame for the poor results we have found. Similarly, the type of coronary artery disease and the nature of the vessels grafted appear to be a typical cross-section of our practice, and there is no indication that bovine grafts were only used in unfavorable circumstances. In addition, platelet studies and clotting studies also demonstrate that this group of patients represented a normal sample of the postoperative population and were not atypically hypercoagulable.

Three patients nominally taking aspirin were, however, found to have normal rather than reduced platelet function, suggesting either that they were noncompliant with their medication or that a standard dose of 75 mg once per

day may be inadequate in certain individuals. Nevertheless, the nature of the postoperative anticoagulant policy did not appear to influence graft patency, and we therefore conclude that the observed poor performance of the bovine internal mammary artery grafts is due to genuine graft failure and unlikely to be due to technique or abnormal coagulation.

The dialdehyde tanning procedure removes the dendritic cells of the bovine internal mammary artery grafts, so rendering them immunologically inert. Rejection is therefore unlikely to be a cause of their failure. However, with exposure of collagen and the inevitable lack of endothelium in the intima, the nonliving tissue of the conduit (despite favorable laboratory studies) must represent a very thrombogenic surface. With this knowledge, poor long-term patency is not surprising, and in view of our results, we cannot recommend further use of this graft. Although bilateral (native) internal mammary artery grafts could be performed, we did not use this approach. This was partly because the right internal mammary artery was often found to be unsuitable in view of the location of the vessels to be grafted and also because of concern over the consequences of sternal devascularization. Although other arterial conduits such as the gastroepiploic artery may be helpful in some instances, there is clearly a need for a satisfactory artificial graft. Nevertheless, we believe that the ideal conduit still remains to be found.

Perfusion Pressure Control by Adenosine Triphosphate Given During Cardiopulmonary Bypass

Kazuhiro Hashimoto, MD, Hiromi Kurosawa, MD, Shigeki Horikoshi, MD, Hisaki Miyamoto, MD, and Kazuhiko Suzuki, MD

Department of Cardiovascular Surgery, Jikei University School of Medicine, Tokyo, Japan

Administration of exogenous adenosine triphosphate (ATP) as a vasodilator during cardiopulmonary bypass was assessed in consecutive adult patients ($n = 24$) who demonstrated a high arterial perfusion pressure (mean, >90 mm Hg). The action of ATP was characterized by rapid induction and stabilization of the blood pressure level. The dose of ATP ranged from 0.68 to 2.68 mg/min. Within 1 minute after the administration, there was a significant reduction in the perfusion pressure from 102 ± 18 mm Hg (mean $\pm$ standard deviation) to 72 ± 19 mm Hg. The ATP was then able to maintain the desired pressure of 69 ± 12 mm Hg at 5 minutes, 67 ± 12 mm Hg at 10 minutes, and consistent values thereafter. After the ATP administration was discontinued, there was a prompt recovery of pressure without bradyar-

rhythmia. The frequency and amount of inotropes used were consistent with the control group ($n = 26$). Although the administration of ATP reduced the increase in serum catecholamine concentration, there were no significant changes in other vasoactive mediators (eicosanoid, angiotensin II, endothelin) between the two groups during cardiopulmonary bypass. There was neither an accumulation of metabolic products (uric acid, phosphate) nor a decrease in the level of divalent cation (Ca^{2+}), which is observed when the cations combine with phosphates or adenosine nucleotides. This study confirmed the efficacy and safety of ATP infusion during cardiopulmonary bypass.

(*Ann Thorac Surg* 1993;55:123-6)

Peripheral vasculature usually constricts during cardiopulmonary bypass (CPB), especially during central cooling. This response is generally believed to be due to the increase in the level of catecholamine [1-4]. To improve the impaired peripheral vascular circulation, several kinds of vasodilators have been used. Although chlorpromazine is an effective vasodilator [5], the negative and uncontrollable inotropic effect is often problematic. α -Adrenergic blocking agents, such as phentolamine or phenoxybenzamine, have delayed initiation periods and prolonged durations of action. Nitroglycerin also has a delayed effect and is unpredictable. The use of prostacyclin has been reported to be beneficial for not only vasodilatation, but also platelet protection, in spite of its high cost [6, 7]. Because rapidly acting vasodilators are clinically important for the acute control of blood pressure, sodium nitroprusside has been used in the United States and other countries [8, 9]. However, the clinical use of sodium nitroprusside has been prohibited in various countries, including Japan, because of the possible toxicity of its metabolite (cyanide) [10-12]. Thus, alternative and cost-effective vasodilators are required.

Adenosine triphosphate (ATP) is a well-known intracellular high-energy molecule. Studies on the cardiovascular

effects of exogenously administered ATP have shown that ATP is a potent vasodilator [13-16] with negative inotropic [17] and chronotropic properties [18]. The concentration of ATP that is required to obtain the negative inotropic and chronotropic effects is rather high compared with the concentration needed to induce vasodilation. Therefore, a small dose of ATP is able to induce vasodilation without manifesting the other effects. In addition, ATP administration may also influence vasoactive mediators, which could additionally affect the vasoactive mechanisms.

This study was designed to evaluate the vasodilative effects of ATP, to then examine its influence on vasoactive mediators, and finally to determine its safe and efficient administration during CPB.

Material and Methods

Fifty consecutive adult patients who underwent open heart operations were included in this study. Four hundred milligrams of ATP (10 mL) was prepared in 90 mL of saline solution. When the mean arterial perfusion pressure exceeded 90 mm Hg, ATP was administered to maintain the mean pressure around 65 mm Hg. Consequently, ATP was used in 24 of the 50 patients.

Anesthesia and Cardiopulmonary Bypass

The patients were premedicated with morphine (0.08 mg/kg) and scopolamine (0.06 mg/kg) 1 hour before

Accepted for publication May 1, 1991.

the induction of anesthesia. Before the induction, a Swan-Ganz catheter was inserted through their right internal jugular vein. Balanced anesthesia was introduced with fentanyl ($10 \mu\text{g/kg}$), diazepam, and pancuronium bromide. A membrane oxygenator, with polypropylene hollow fibers and polyvinyl chloride tubing, was used for the operation. Before the initiation of the bypass, 2 g of hydrocortisone and heparin (2 mg/kg) were administered intravenously. The operation was performed in moderate hypothermia (around 28°C) with partial hemodilution (estimated hematocrit, 0.25), and the activated clotting time was maintained at more than 400 seconds with intravenous additions of heparin. Cardiac arrest was obtained with a potassium cardioplegic solution. The heart was then topically cooled. Finally, we tried to maintain the perfusion flow at $80 \text{ mL} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$ while performing the total bypass.

Measurements of Vasoactive Mediators

In 15 patients (8 with ATP administration and 7 controls), the levels of the vasoactive mediator metabolites of eicosanoid (thromboxane B_2 and prostaglandin $F_{1\alpha}$), endothelium-derived constrictive factor (endothelin 1), catecholamine (norepinephrine and epinephrine), and angiotensin II were measured. Measurements were carried out after the anesthesia, 5 minutes after the initiation of CPB, and 5 minutes before the cessation of CPB. Inotropes were not used during this period. The methods used to measure these substances are described elsewhere [4, 19].

Adenosine Triphosphate Metabolism

After intravenous administration, the capillary endothelial cells rapidly hydrolyze ATP to adenosine with the consequent release of three molecules of phosphoric acid. Although adenosine is rapidly deaminated and converted to hypoxanthine, which is subsequently oxidized to uric acid [20], adenosine nucleotides and phosphates may form complex divalent cations such as calcium. In all of the patients, serum concentrations of ionized calcium, phosphate, and uric acid were measured at the beginning and end of CPB.

Statistical Methods

All values were expressed as the mean $\pm$ standard deviation. The unpaired Student's *t* test was used to determine the statistical significance of differences between the two groups. Differences with a *p* value of 0.05 or less were considered significant. The coefficient of correlation between two variables was calculated using Spearman's rank-difference technique.

Results

There were no differences in either the operative procedures or the ages between the experimental and control groups (Table 1). The body temperatures and perfusion flows during CPB were also identical. The average aortic clamping time was 76 ± 39 minutes in the control group and 90 ± 40 minutes in the ATP group (*p* = 0.23). The

Table 1. Operative Procedures

average perfusion time was also shorter (*p* = 0.11) in the control group (125 ± 59 minutes) than in the ATP group (154 ± 59 minutes). The initial arterial pressure was 52 ± 11 mm Hg in the control group and 55 ± 16 mm Hg in the ATP group, with peak pressures of 73 ± 9 mm Hg and 102 ± 18 mm Hg, respectively (*p* < 0.01).

In the ATP group, the dose of ATP ranged from 0.68 to 2.68 mg/min with a mean dose of 1.28 ± 0.56 mg/min. The total mean dose of ATP was 78 ± 57 mg (from 6.6 to 240 mg) with a mean infusion period of 55 ± 25 minutes. Figure 1 displays the changes in mean arterial pressures that were regulated by the administration of ATP during CPB. A significant drop in arterial pressure was observed within 1 minute (usually 20 to 30 seconds) after the initiation of ATP administration. The perfusion pressure was then maintained at the desired pressure of 68 ± 16 mm Hg (at 3 minutes) and remained consistent thereafter. After the discontinuation of ATP administration, a prompt recovery in arterial pressure was observed. Because the patients did not display episodes of either second-degree or complete atrioventricular blockage or bradycardia after CPB, they did not require any additional treatments. The frequency of inotrope use was not signif-

Fig 1. Transit of arterial perfusion pressure maintained by adenosine triphosphate (ATP) administration. Administration of ATP was characterized by rapid induction and stabilization of the blood pressure level; after discontinuation, a prompt recovery in pressure was observed.

ATP = adenosine triphosphate; Change = value change from CPB on to CPB off; CPB = cardiopulmonary bypass.

icantly different between the two groups (ATP, 18 of 24 patients; control, 20 of 26).

The increase in the concentrations of serum thromboxane B₂ and prostaglandin F_{1α} concentrations during CPB was not influenced by the administration of ATP. In addition, the concentrations of angiotensin II and endothelin also did not display significantly varying results. The increments of norepinephrine and epinephrine, however, were significantly less in the ATP group during CPB (Table 2).

The measured serum concentrations of calcium, phosphate, and uric acid were not different between the two groups both preoperatively and postoperatively (Table 3). There was little correlation between the total ATP dose and the increase in the level of uric acid (preoperative minus postoperative value) during CPB ($r = -0.15$; $p = 0.51$).

Comment

Adenosine triphosphate-induced vasodilatation is characterized by rapid induction and stabilization of the blood

Table 3. Levels of Uric Acid, Calcium, and Phosphate

Variable	ATP Group		Control Group	
	CPB On	CPB Off	CPB On	CPB Off
Uric acid	5.3 ± 1.3	5.4 ± 1.0	5.4 ± 1.9	5.6 ± 2.0
Calcium	3.0 ± 0.3	3.4 ± 0.3	3.0 ± 0.3	3.7 ± 1.7
Phosphate	2.5 ± 0.6	2.3 ± 0.7	2.5 ± 0.9	2.3 ± 1.0

ATP = adenosine triphosphate; CPB = cardiopulmonary bypass.

pressure level, which rapidly reverses when infusion of the drug is discontinued. This abrupt response is due to the rapid metabolism of ATP [20]. The mechanisms of ATP vasodilatation are mainly endothelium-dependent relaxation caused by endothelium-derived relaxing factor release [13, 14, 16, 21]. Endothelium-derived relaxing factor has been previously described as a vasodilator messenger between the endothelial cell receptors (endothelial-dependent relaxing agents such as acetylcholine, histamine, peptides, adenosine diphosphate, and ATP) and the effector (vascular smooth muscle cells). Endothelium-derived relaxing factor consequently increases the level of cyclic guanosine monophosphate in the smooth muscle and dilates the vessels [16, 21]. In addition to these actions, ATP produces peripheral vasodilatation by inhibiting of the sympathetic nervous system [13]. Perhaps the effectiveness of ATP as a vasodilator is influenced by some modulation (hypertension or atherosclerosis) of the endothelium and sympathetic nerve intensity during CPB. However, because all our patients did not show a blunt reaction to ATP administration, the effectiveness of ATP's vasodilative action was not altered by individual modulation of the endothelium or by general anesthesia during CPB.

Sodium nitroprusside is also a short-acting antihypertensive agent with an effect that ceases immediately after the infusion is stopped. However, when administered in high doses, it is potentially toxic because the normal metabolic pathways can become overloaded. In addition, free cyanide is formed, which is capable of destroying cytochromes [10-12]. Moore and associates [12] examined the effect of hypothermia on the metabolism of sodium nitroprusside during CPB. They concluded that the non-enzymatic release of free cyanide from sodium nitroprusside was not inhibited by hypothermia, whereas the enzymatic detoxification of free cyanide was possibly delayed. As Fukunaga and colleagues [15] demonstrated, ATP has a more rapid initiation period and shorter recovery time than sodium nitroprusside. Moreover, the administration of ATP maintained a remarkably stable blood pressure throughout the infusion [15].

For the treatment of reentrant tachycardia, the dose of ATP bolus injection has been reported to be between 15 to 30 mg [18]. However, the continuous low-dose infusion (0.68 to 2.68 mg/min) of ATP during CPB in this study did not induce bradycardia after aortic declamping. In addition, because negative inotropic and chronotropic effects were not reported during ATP-induced hypotensive anesthesia, the influence of ATP on postischemic cardiac functions was considered negligible [22-24]. Most hemodynamic changes induced by ATP infusions are related to changes in vascular resistance rather than changes in myocardial contractility [22-24].

Other investigators have demonstrated that ATP administration not only inhibits norepinephrine release in blood vessels and other organs [25] but also inhibits the action of epinephrine on vascular smooth muscles in experimental animals [23]. It was also reported that ATP administration during operation on a pheochromocytoma depressed the induction of both hypertension and ar-

rhythmia induced by catecholamine release [26]. During CPB, because the increase in the level of catecholamine induces an increase in vascular resistance [1-4], the administration of ATP is very effective and theoretically recommended. Although low levels of catecholamine were detected in this study, these low concentrations might be involved in protecting against reperfusion injury [27, 28]. The administration of ATP did not influence the other vasoactive mediators.

There was neither an increase in serum uric acid nor a decrease in the level of serum calcium in the ATP group after CPB. These were the same results observed in the control group. Furthermore, we did not detect any complications due to the process of ATP metabolism or the metabolites. Therefore, the side effects of ATP administration were negligible.

In conclusion, the administration of ATP during CPB is a very effective procedure to control high blood pressure. Because the application of ATP is both effective and safe, this drug can be used as a substitute for sodium nitroprusside.

Effects of Cryothermia During Cold Cardioplegia on Epicardial and Intramural Coronary Arteries

Patricia F. A. Bakker, MD, Hans R. J. Elbers, MD, Freddy E. E. Vermeulen, MD, and Etienne O. Robles de Medina, MD

Heart Lung Institute, University Hospital Utrecht, and Departments of Cardiac Pathology and Cardiac Surgery, St. Antonius Hospital, Nieuwegein, The Netherlands

Cryosurgery is playing an increasingly important role in the surgical treatment of various supraventricular and ventricular tachyarrhythmias. The short-term and long-term effects of cryogenic injury on epicardial and intramural coronary arteries were studied in 22 dogs. Transmural cryolesions encompassing a posterolateral branch of the circumflex coronary artery were produced in the inferior left ventricular wall during extracorporeal circulation and cold cardioplegic arrest. The mean epicardial cryolesion area $\pm$ standard deviation was $10.4 \pm 1.8 \text{ cm}^2$. The mean epicardial coronary artery diameter $\pm$ standard deviation measured $1.2 \pm 0.4 \text{ mm}$. At 6 hours, no

important structural changes were noted in any of 6 dogs. At 48 hours, 1 of 2 epicardial coronary arteries showed recent thrombus. At 1, 3, and 6 months, the epicardial coronary arteries were occluded due to thrombosis and intimal hyperplasia in 13 of 14 dogs. A limited degree of recanalization was observed. At all follow-up intervals, the intramural coronary arteries exhibited a histologic pattern similar to that of the epicardial coronary arteries. It is concluded that the exposure of major epicardial coronary arteries to cryoinjury during cold cardioplegic arrest should be avoided where possible.

(*Ann Thorac Surg* 1993;55:127-30)

Since cryoablation became part of the surgical armamentarium to treat cardiac arrhythmias [1, 2], a rapidly growing literature has been witnessed on histopathologic and electrophysiologic characteristics of cardiac cryolesions, factors contributing to cryogenic effects, and adverse effects. Studies of early and late cryogenic effects on the coronary arteries have been prompted by concern over the possible detrimental results. Several reports deal with the reaction of the epicardial coronary vessels to cryolesions created under normothermic conditions [3-7]. With one exception [4], no or only mild untoward effects were reported in these experimental studies. Clinically, cryoablation of subendocardial, intramural, and subepicardial anatomic substrates of ventricular tachycardia is generally performed under cold cardioplegic arrest. Therefore, a more severe cryoinjury can be expected [8, 9]. This is supported by the more severe intimal hyperplasia and coronary artery stenosis after freezing during cold cardioplegic arrest in the single study in which the long-term effects of cryolesions produced during cold cardioplegic arrest and normothermia are described [5].

In the present study we investigated the short-term and long-term effects of large transmural cryolesions created in the inferior left ventricular wall during cold cardioplegic arrest on epicardial and intramural coronary arteries in dogs.

Material and Methods

Twenty-two mongrel dogs with a weight between 20 and 31 kg were enrolled in the study. All animals received

humane care in compliance with the "Principles of Laboratory Animal Care" formulated by the National Society for Medical Research and the "Guide for the Care and Use of Laboratory Animals" published by the National Institutes of Health (NIH publication No. 85-23, revised 1985).

Experimental Procedure

A left lateral thoracotomy was performed under high-dose sufentanil anesthesia and controlled ventilation. During extracorporeal circulation and moderate hypothermia (24°C), cold cardioplegic arrest was induced with St. Thomas' Hospital cardioplegic solution No. 2 (4°C), infused into the aortic root. Ringer's lactate (4°C) was used for continuous topical cooling. The interventricular septal temperature was monitored and did not exceed 18°C during aortic cross-clamping. The mean cross-clamp time $\pm$ standard deviation was 39 ± 7 minutes. A 15-mm cryoprobe (Frigitronics Inc, Shelton, CT), cooled to -70°C for 3 minutes by expanding nitrous oxide, was used to apply two to four epicardial cryolesions and two to four endocardial cryolesions (through the mitral orifice) in the inferior left ventricular wall at the site of the posterior papillary muscle. This resulted in a transmural lesion with a mean epicardial lesion area $\pm$ standard deviation of $10.4 \pm 1.8 \text{ cm}^2$. In small dogs particularly, a 5-mm and a 15-mm probe were used for endocardial freezing. The cryolesion included at least one large ventricular branch of the circumflex coronary artery.

Six dogs were allowed to survive for 6 hours, 2 dogs for 2 days, 3 dogs for 1 month, 5 dogs for 3 months, and 6 dogs for 6 months. Anticoagulants and platelet aggregation inhibitors were not given.

Pathologic Examination

At the end of follow-up, all dogs were sacrificed by an overdose of anesthetic, and the hearts were excised im-

mediately and examined macroscopically. The area containing the cryolesion was identified. One tissue block, which included at least one large posterolateral branch of the circumflex coronary artery, was excised from the cryolesion. A second tissue block, which included a segment of the left anterior descending coronary artery, was removed from the anterior left ventricular wall at a comparable level and served as control. These tissue blocks were oriented so that cross-sections of the epicardial coronary arteries would be obtained. The heart was transversely sectioned in 1-cm-thick slices. The presence of myocardial lesions distal to the cryolesion was examined. In addition, four transmural tissue blocks were taken from the cryolesion and from the anterior left ventricular wall at a comparable level (for control). The tissue blocks were fixed in 10% buffered formaldehyde and processed by routine histologic techniques for light microscopy. Serial sections (5 μ m thick) were cut and stained with hematoxylin and eosin, elastin van Gieson, and Masson trichrome. Six sections of each tissue block were studied. Representative specimens were fixed in Karnovsky's solution for plastic embedding techniques.

Results

At all follow-up intervals, the epicardial and intramural coronary arteries in the control specimens taken from the anterior left ventricular wall were unremarkable. No lesions distal to the cryolesion were found in the left ventricular wall in any of the dogs.

At 6 hours after cryothermic exposure ($n = 6$), light microscopic examination of the posterolateral branch of the circumflex coronary artery revealed no morphologic changes in 3 of 6 dogs. Subintimal edema and hemorrhage were observed in the remaining 3 animals. In addition, a mild degree of inflammation of the coronary media was found in 2 cryolesions. No thrombi were observed in any of the 6 examined arteries.

Forty-eight hours after operation ($n = 2$), both hearts studied showed edematous changes in the subintimal layer and a mild degree of medial inflammation of the posterolateral branch exposed to cryothermic injury. In addition to the presence of edema and inflammation, 1 of these animals showed a recent thrombus in the injured artery (Fig 1). The other dog showed a mural thrombus in a major coronary vein in the exposed area. Furthermore, mild fragmentation of the internal elastic lamina was seen in 1 animal.

At 1-month follow-up ($n = 3$), stenosis mainly due to concentric intimal hyperplasia was detected in 2 of 3 dogs. Additionally, there was thrombotic occlusion of the arterial lumen with some degree of recanalization in all 3 animals (Fig 2).

At 3 months after freezing ($n = 5$), the coronary artery intima showed severe hyperplasia in all 5 dogs (Fig 3). In 1 dog, the intimal hyperplasia was concentric. In addition, the posterolateral branches showed almost complete occlusion by partially recanalized thrombi in 4 dogs.

At 6 months postoperatively ($n = 6$), the posterolateral branches in the cryolesion showed severe concentric as

Fig 1. Photomicrograph of a posterolateral coronary arterial branch 48 hours after cryogenic injury, showing recent thrombus. (Elastin van Gieson; $\times 100$ before 52% reduction.)

well as eccentric intimal hyperplasia and virtually complete occlusion by organized thrombi in all 6 animals (Fig 4). In 1 specimen, fragmentation of the internal elastic lamina was noted.

At all follow-up intervals, the intramural coronary arteries in the cryolesion showed histologic alterations similar to those in the epicardial coronary arteries. The diameter of the epicardial coronary arteries, however, was 1.2 ± 0.4 mm, whereas the diameter of the intramural coronary arteries was generally smaller (maximal diameter, 0.8 mm). Nonetheless, some of the intramural coronary arteries involved in the cryolesion remained patent although their lumen was compromised by intimal hyperplasia and thrombosis at 1, 3, and 6 months postoperatively. The light microscopic observations of the myocardium surrounding the intramural coronary arteries at the cryolesion site at various follow-up intervals were as follows. At 6 and 48 hours, interstitial edema and widespread interstitial hemorrhage were present. In addition, at 48 hours transmural necrosis of the ablated myocar-

dium and infiltration with segmented neutrophilic granulocytes were observed. Light microscopic examination at 1 month showed fibrosis at the lesion margin, whereas the center of the lesion still consisted of necrotic myocardium. At 3 and 6 months, the entire lesion was scarred. Changes of the intramural coronary arteries were not related to their location in the cryolesion.

Comment

In 1948, Hass and Taylor [3] were the first to describe the effects of cryoinjury on the myocardium and epicardial coronary arteries. Since then, there have been relatively few reports dealing with the effects of freezing on the coronary arteries [4-7]. The paucity of reports is the more conspicuous if one takes into account the many factors that play a role in the final outcome of hypothermal exposure. A review of the literature on the effects of cryogenic injury shows that the intensity of the injury,

Fig 4. Characteristic histologic appearance of an epicardial posterolateral coronary artery 6 months after cryothermic exposure, demonstrating complete occlusion by organized thrombus. (Elastin van Gieson; $\times 100$ before 52% reduction.)

and hence the structural alterations of the artery, are mainly dependent on the rate of cooling, the depth of cooling, the duration at low temperature, the rate of thaw, the number of successive cooling cycles, and the size of the exposed artery [4-12].

Generally, minimal morphologic alterations of the epicardial coronary arteries have been described in studies on the effects of freezing under normothermic conditions [3, 5-7]. An exception is the study of Mikat and co-workers [4]. They described partial (50%) to complete thrombotic occlusion of the lumen of small and medium-sized coronary arteries in dogs 1 week after freezing. This was followed at 1 month by an increase in mural fibrosis and intimal plaque formation. Also, recanalized thrombi were seen. At 8 to 12 weeks, plaques were still present, but the degree of fibrosis decreased. The lumen of the large and medium-sized coronary arteries, however, remained patent. Cryolesions were applied using a 5-mm probe, cooled to -50°C for 90 to 120 seconds. Two successive cooling cycles were used, which probably explains the more detrimental effects on the coronary arteries.

Holman and associates [5] reported 10% to 60% stenosis of the distal left anterior descending coronary artery in dogs 6 months after cryothermic exposure. Cryolesions were produced with a 4-mm probe cooled to -60°C for 3 minutes. This is the single study on the long-term effects on the epicardial coronary arteries of freezing during cold cardioplegic arrest. Coronary artery stenosis was due to intimal hyperplasia, which was concentric in 2 of 4 dogs. In 1 dog only, the coronary artery was normal. In addition, two small diagonal branches showed 80% stenoses, illustrating the importance of vessel size. The major coronary artery branches remained patent. No morphologic alterations of the coronary arteries were seen in the same study after freezing during normothermia.

The present study provides further evidence for severe cryogenic injury to the coronary arteries when freezing is performed under cold cardioplegic arrest. The histologic picture at 1, 3, and 6 months was dominated by thrombosis and partial recanalization. Also, eccentric as well as concentric intimal hyperplasia were observed. The latter excludes that organized thrombi were the only cause of intimal hyperplasia. In contrast to the study results of Holman and associates [5], most of the major coronary arteries (1.2 ± 0.4 mm in diameter) were almost completely occluded. The presumably longer aortic cross-clamp time (mean, 39 minutes) in our study may have been responsible for the more serious morphologic alterations of the epicardial coronary arteries. The rate of thaw is extremely slow during the period of cross-clamping. The intramural coronary arteries involved in the lesion exhibited similar changes to the epicardial coronary arteries. The fact that the intramural coronary arterial changes were also observed at an early stage suggests that they resulted directly from cryogenic injury rather than being secondary to fibrosis of the lesion [13]. The observed serious intramural coronary artery alterations warrant caution even when cryolesions are applied endocardially, because these lesions have been reported to extend trans-

murally [14, 15]. Further studies are needed on the effects on the epicardial coronary arteries of large endocardial cryolesions applied during cold cardioplegic arrest. Research is required also to evaluate whether administration of antithrombotic agents may prevent or mitigate the occurrence of coronary artery thrombosis due to cryosurgery.

The absence of myocardial lesions distal to the cryolesion does not imply functional capability of the coronary artery exposed to freezing, because of the presence of an extensive coronary artery collateral blood supply in the dog [16], and should therefore not detract from the potential risks of stenosis and occlusion of epicardial coronary arteries in humans.

Although cryoablative methods greatly contribute to the management of both supraventricular and ventricular tachyarrhythmias, the risk of coronary artery occlusion reported herein should be taken into account when clinical application of cryolesions encompassing major coronary arteries is considered, particularly when these arteries supply viable myocardium.

This study was supported by grant no. 83-120 of The Netherlands Heart Foundation and is part of project 11 of the Interuniversity Cardiology Institute of The Netherlands.

We thank Jan R. Tuntelder for his excellent technical assistance and Antoinette van Putten for her expert assistance in the preparation of the text. We also thank Professor C. Borst, MD, for critically reviewing the manuscript.

Improved Tracheal Allograft Viability in Immunosuppressed Rats

Christopher J. Davreux, BSc, Norman H. Chu, Thomas K. Waddell, MD, Eckhard Mayer, MD, and G. Alexander Patterson, MD

Division of Thoracic Surgery, Department of Surgery, University of Toronto, Toronto, Ontario, Canada

Airway ischemia has been a common cause of morbidity and mortality in clinical lung transplantation. The present study examined the effects of cyclosporin A (CsA) and methylprednisolone (MP) on the viability of the devascularized trachea after heterotopic transplantation and omentopexy. Thirty-six tracheal segments were harvested from 18 donor Lewis rats, wrapped in omentum, and heterotopically implanted into the abdomen of recipient rats. Tracheal segments were randomly allocated into one of six recipient groups ($n = 6$): Lewis syngeneic controls, and five groups of Brown Norway recipients, receiving either no treatment, CsA alone ($5 \text{ mg} \cdot \text{kg}^{-1} \cdot \text{day}^{-1}$ or $15 \text{ mg} \cdot \text{kg}^{-1} \cdot \text{day}^{-1}$), or CsA in combination with MP ($5 \text{ mg CsA} + 1 \text{ mg MP per kg/day}$ or $15 \text{ mg CsA} + 2 \text{ mg MP per kg/day}$, respectively). After

14 days, the tracheal segments were histologically evaluated. Epithelial thickness and the degree of epithelial regeneration were significantly different ($p < 0.05$) between the syngeneic control group and the untreated Brown Norway group. Without immunosuppression there was virtually no epithelium, whereas low-dose immunosuppression yielded intermediate viability, and with high dose CsA and MP we observed improved tracheal viability. In this high-dose group, the epithelium was thicker than in even the syngeneic control group. These results indicate that, in heterotopic tracheal allografts, viability may be improved with an optimum combination of CsA and MP.

(*Ann Thorac Surg* 1993;55:131-4)

In the last decade, lung transplantation has become a viable option for patients with end-stage pulmonary disease [1]. Improved strategies of allograft preservation and surgical technique have resulted in improved success rates after single- and double-lung transplantation [2]. In the early experience of many centers, bronchial anastomotic complications secondary to ischemia were major causes of morbidity and mortality [3, 4].

Without surgical reconnection of the bronchial circulation, the donor bronchus is at risk of ischemia until local tissue revascularization can be achieved. This process can take 12 to 15 days [5] but can be accelerated by bronchial omentopexy. In the interim, the bronchus is dependent on retrograde collateral perfusion from the pulmonary circulation. Parenchymal pulmonary pathology (eg, rejection, infection, or poor preservation) may decrease pulmonary to bronchial collateral flow. In addition, rejection directed against the bronchus itself may also impair the ingrowth of new vessels from surrounding tissues. Thus, avoidance of rejection in the early postoperative period may be important in preventing ischemic complications of the airway.

Corticosteroids have been employed widely as potent immunosuppressive agents. Previously most programs avoided the routine use of corticosteroids during the early postoperative period because of the negative impact of these agents on bronchial anastomotic healing [6, 7]. It

has also been assumed that steroids would impair neovascularization, yet a number of programs [8], including our own [9], have recently determined that early routine corticosteroid use is, in fact, associated with improved airway healing.

In this study, we examined the role of methylprednisolone (MP) and cyclosporin A (CsA) on the epithelial viability of heterotopic tracheal allografts.

Material and Methods

The heterotopic tracheal transplant model with omentopexy [10] was employed using a technique modified for rats [11]. All experiments were performed on male (250 to 300 g) inbred Lewis rats (Charles River Canada Inc, St-Constant, PQ, Canada) and Brown Norway rats (Harlan Sprague Dawley Inc, Indianapolis, IN). Thirty-six Lewis tracheal segments were harvested and implanted into the omentum of 6 Lewis rats and 30 Brown Norway rats. Animals were randomly allocated into experimental groups, as summarized in Table 1. All animals received humane care in compliance with the "Principles of Laboratory Animal Care" formulated by the National Society for Medical Research, the "Guide for the Care and Use of Laboratory Animals" prepared by the National Academy of Science and published by the National Institutes of Health (NIH publication No. 85-23, revised 1985), and the "Guide to the Care and Use of Experimental Animals" formulated by the Canadian Council on Animal Care. The experimental protocol was approved by the Animal Care Committee of The Toronto Hospital.

Table 1. Experimental Design

Group	n ^a	Donor	Recipient	Cyclosporine ^b (mg · kg ⁻¹ · day ⁻¹)	Prednisolone ^b (mg · kg ⁻¹ · day ⁻¹)
1	6	Lewis	Lewis	...	...
2	6	Lewis	BN	...	...
3	6	Lewis	BN	5	...
4	6	Lewis	BN	5	1
5	4	Lewis	BN	15	...
6	4	Lewis	BN	15	2

^a Number of animals that survived all 14 days. ^b All doses were given daily subcutaneously, beginning 1 day preoperatively through 14 days postoperatively.

BN = Brown Norway.

Donor Procedure

Lewis rats received heparin (500 UI/kg intraperitoneally) and sodium pentobarbital (65 mg/kg intraperitoneally). In a sterile fashion the trachea was exposed to its bifurcation and a 3.0-cm or greater length was excised and flushed with 10 mL of isotonic saline solution. The trachea was then stretched *ex situ* to its original length and attached to two metal stretchers (U shaped, no. 4 surgical stainless steel wire, 22 gauge; Ethicon, Peterborough, Ont, Canada) and divided into two 1.4-cm lengths (one upper and one lower tracheal segment) for implantation into two recipients.

Recipient Procedure

Brown Norway rats were anesthetized in an induction chamber with halothane (3%) followed by continuous anesthesia with 2% to 3% halothane in oxygen with spontaneous ventilation. After an upper midline abdominal incision, the stretched tracheal segment was wrapped in greater omentum and then secured with two 6-0 Prolene (Ethicon) stitches. The peritoneum and abdominal musculature were closed with 5-0 Prolene interrupted sutures, and the skin was closed with staples.

Drug Administration

Cyclosporin A (Sandimmune IV; Sandoz Canada Inc, Dorval, PQ, Canada) was diluted to 10 mg/mL with castor oil and MP (Solu-Medrol; Upjohn Canada, Don Mills, Ont, Canada) was diluted in sterile water to 2 mg/mL. These were freshly prepared before use and injected subcutaneously daily, beginning 1 day before the operation. No antibiotics were given.

Sacrifice Operation

After 14 days recipient rats were anesthetized in an induction chamber with halothane (3%), followed by continuous anesthesia with halothane (2% to 3%) in oxygen with spontaneous ventilation. Using a lateral abdominal incision, the tracheal segment, wire stretcher, and surrounding omentum were excised and fixed in 5% acetic acid/95% methanol. The animal was then exsanguinated.

Histologic Assessment

We attempted to quantify the viability of the heterotopic allografted trachea by measuring epithelial thickness and

by subjectively assessing and evaluating the epithelial and submucosal histology. Microscopic slides were made from longitudinal sections of the trachea and adherent omentum and stained with hematoxylin and eosin. Assessment was performed by two blinded observers in the following manner.

EPITHELIAL THICKNESS. Four areas between the cartilaginous rings were chosen randomly in the center of the longitudinal segments. Length and area of the epithelium were independently measured, and epithelial thickness was calculated (thickness = area/length). Computer-assisted morphometry was employed, using an MTI-65 camera (DAGE-MIT, Michigan City, IN), Leitz Colourlux K microscope (Leitz, Wetzlar, Germany), and MultiSync 3D videoscreeen (NEC Information Systems, Boxborough, MA) connected to a HiPad Digitizer pad (Houston Instruments, Austin, TX) via a NEC Powermate 386/20 computer with Bioquant IV morphometry software (R & M Biometrics, Nashville, TN).

EPITHELIAL REGENERATION. The epithelium was assessed according to an established grading system [11] as follows: 0, no epithelium, single nonconfluent epithelial cells; 1, confluent single layer nonciliated epithelium; 2, confluent multilayer nonciliated epithelium; and 3, normal mucociliary epithelium.

Statistical Analysis

All data are presented as mean and standard error (SEM). Statistical analysis was performed using the SAS software package (SAS Institute, Cary, NC). If an overall *F* test was significant in an one-way analysis of variance, selected comparisons were performed between treatment groups and two control groups—syngeneic transplants and untreated allografts. A treatment effect was declared to be significant at the 5% level.

Results

Thirty-six rats underwent tracheal implantation with an operative survival of 100%. Four animals treated with high-dose CsA (15 mg · kg⁻¹ · day⁻¹) died within 7 days with widespread intraabdominal infection (2 in both the with and without MP groups [groups 5 and 6]); these animals were excluded from our analysis. Macroscopically, rats treated with MP were grossly distinguishable from those not receiving steroids. In steroid-treated animals reduced inflammation and fewer peritoneal adhesions were noted at sacrifice 14 days postoperatively.

The thickness of the tracheal epithelium was found to be significantly less in the two groups (groups 2 and 3) with the lowest levels of immunosuppression than in the Lewis to Lewis syngeneic control animals (Fig 1). Epithelial thickness in the intermediate immunosuppression allograft groups (groups 4 and 5) was not significantly different from syngeneic controls. Interestingly, in the 4 surviving animals treated with both high-dose CsA and high-dose MP (group 6), the epithelial thickness was increased and significantly thicker even than in syngeneic controls.

Fig 1. Average epithelial thickness in heterotopic tracheal isografts or allografts with or without immunosuppression. Data are presented as mean $\pm$ standard error. (BN = Brown Norway; CsA = cyclosporin A; LEW = Lewis; MP = methylprednisolone; TX = treatment; * $p < 0.05$ when compared with syngeneic controls.)

The epithelial regeneration assessment demonstrated almost complete destruction of the epithelium after allografting without immunosuppression (Fig 2). Note that even at 14 days, the epithelium is not morphologically normal (a regeneration score of 3 is considered normal) in syngeneic transplants. Compared with syngeneic controls, untreated allografted animals had a significantly lower regeneration score. Similar to the thickness data, group 6, with the highest level of immunosuppression, had a significantly higher regeneration score compared with syngeneic controls. Only in this group has the epithelium returned to normal. There were no significant differences in regeneration score in the intermediate immunosuppression groups. Figure 3 illustrates three typical examples of regeneration after allotransplantation.

Fig 2. Average epithelial regeneration score in heterotopic tracheal isografts or allografts with or without immunosuppression. Data are presented as mean $\pm$ standard error. (* $p < 0.05$ compared with syngeneic controls; abbreviations are as in Figure 1.)

Fig 3. Representative examples of tracheal epithelium. (A) Lewis trachea implanted into Brown Norway recipient without immunosuppression. Only a monolayer of epithelial cells is present. (B) Lewis trachea implanted into Lewis recipient without treatment. The epithelium is made up of several layers of nucleated cells but cilia are not present. (C) Lewis trachea implanted into Brown Norway recipient treated with cyclosporin A, $15 \text{ mg} \cdot \text{kg}^{-1} \cdot \text{day}^{-1}$, and methylprednisolone, $2 \text{ mg} \cdot \text{kg}^{-1} \cdot \text{day}^{-1}$. Virtually normal epithelium with basal nuclei and ciliated cells is seen.

Comments

Before the first successful clinical lung transplantation in 1983, bronchial anastomotic complications contributed directly to the death of most patients surviving more than 10 days after the operation [12]. The early success of the Toronto lung transplantation program may have been in part due to the routine use of bronchial anastomotic omentopexy. Earlier revascularization of the donor bronchus and enclosure by omentum of partial anastomotic dehiscence were powerful arguments for using omentopexy routinely. Yet, even with omentopexy, bronchial anastomotic complications proved to be a major cause of morbidity and mortality [3].

In the past, corticosteroids were avoided in the early postoperative period because of evidence in canine auto-transplantation models that such therapy resulted in impaired bronchial healing [6, 7]. Recently, however, a number of programs, including our own, have followed the lead of the San Antonio group [3] and employed corticosteroids routinely during the posttransplantation period with excellent results.

In the present study, we attempted to quantify viability of a heterotopic tracheal allograft by making quantitative and qualitative assessments of the epithelium. We have previously shown these measures to correlate with a direct measurement of tracheal vascularity [11]. In this study we did not directly measure tracheal vascularity. Here, we demonstrated that uncontrolled rejection significantly impairs the regeneration of the tracheal epithelium. Immunosuppression, on the other hand, allows regeneration to occur. We found improved tracheal via-

bility in high-dose CsA groups with or without MP compared with the untreated group.

An unexpected finding was the improved tracheal viability in group 6 (high-dose CsA and high-dose steroid). In this group, the tracheal epithelium was even thicker and the morphology more normal than in the syngeneic control group. Possible explanations for this observation include a reduction in peritracheal inflammation with improved angiogenesis or a direct trophic effect on the tracheal epithelium.

Corticosteroids have been shown to have antiangiogenic properties that vary greatly between steroid molecules. For example, dexamethasone has minimal angiogenic effects compared with cortisone [13]. In this model of heterotopic tracheal allotransplantation, viability was observed to be improved with a high dose of CsA and MP after omentopexy. Whether steroid therapy alone (without cyclosporine) would have the same effect is not known. However, this cyclosporine-corticosteroid combination regimen was chosen because it mimics that employed in most clinical lung transplant programs.

The epithelial regeneration scoring system used in this study is based on descriptions of repair after mechanical and toxic injury to rat and hamster trachea [14, 15]. Previous work has shown that the regeneration of epithelium after devascularization and syngeneic heterotransplantation is not completed by 14 days [11]. In this study we confirmed that the epithelial morphology has not returned to normal by this time. Fourteen days, however, was found to be sufficient time for the development of a strong immune response, as evidence of early rejection was apparent histologically in the allografted study groups by this time. The possibility exists that the epithelium had regenerated but was subsequently destroyed by rejection in the allogenic groups not given high-dose immunosuppression.

The heterotopic rat tracheal transplant model offers the advantages of simplicity, controlled MHC disparities, and low cost. It allows the evaluation of tracheal viability, independent of the complexities of pulmonary to bronchial retrograde circulation. On the other hand, such an avascular graft may be less susceptible to rejection than bronchial tissue included in a pulmonary allograft. It also requires the implantation of a foreign body (wire "stretchers") into the abdominal cavity. We have found these stretchers necessary to prevent the natural retraction of the trachea wall between cartilaginous rings [11].

Prophylactic antibiotics were not administered in this study. Despite sterile surgical technique, 2 rats in each of the groups receiving high-dose CsA died with intraabdominal sepsis. The dose administered to these animals was chosen arbitrarily to minimize acute rejection. It exceeds the current dosage used in human lung transplantation. It is interesting that the addition of high-dose corticosteroid was not associated with a higher incidence of intraabdominal sepsis.

In conclusion, in this model of heterotopic tracheal allotransplantation with omentopexy without any immunosuppression, there was poor tracheal viability as determined by epithelial thickness and subjective histological

assessment. Low-dose CsA ($5 \text{ mg} \cdot \text{kg}^{-1} \cdot \text{day}^{-1}$) and MP ($1 \text{ mg} \cdot \text{kg}^{-1} \cdot \text{day}^{-1}$) result in similar tracheal viability to syngeneic controls. High-dose immunosuppression (CsA, $15 \text{ mg} \cdot \text{kg}^{-1} \cdot \text{day}^{-1}$, and MP, $2 \text{ mg} \cdot \text{kg}^{-1} \cdot \text{day}^{-1}$) produced improved tracheal viability in comparison with syngeneic controls.

After allografting, the prevention of rejection with adequate immunosuppression is necessary to allow successful regeneration. Specifically, the addition of corticosteroids does not appear to impair regeneration.

Argon Beam Coagulation Compared With Cryoablation of Ventricular Subendocardium

Paul J. Hendry, MD, Eileen M. Mikat, PhD, Mark P. Anstadt, MD,
Mark D. Plunkett, MD, and James E. Lowe, MD

Department of Surgery, Duke University Medical Center, Durham, North Carolina

The Argon Beam Coagulator uses radiofrequency energy to excite argon gas that may be used for ventricular ablation. The effects of power level and number of applications of the Argon Beam Coagulator were compared with cryothermia. Ten mongrel dogs underwent cardiac extirpation. The endocardial surfaces of 5 hearts were used for the creation of lesions using the Argon Beam Coagulator at five power levels with either one or two applications. Five hearts were used for endocardial and epicardial lesions using cryothermia (15-mm-diameter probe at -70°C) for 1, 2, 3, or 4 minutes. The Argon Beam Coagulator lesions showed an increase in depth with increasing power levels (2.25 ± 1.05 mm at 50

W to 6.64 ± 0.75 mm at 150 W) and number of applications (maximum depth of 6.64 ± 0.75 mm with one application, 11.2 ± 1.1 mm with two applications). Cryothermia lesions were similar in depth regardless of duration or site of application (range, 6.1 to 10.2 mm). Both techniques resulted in homogeneous and well-demarcated lesions. These data show that the Argon Beam Coagulator results in discrete endocardial lesions, which may be created quickly and reproducibly. This may be a useful alternative for the operative ablation of endocardial scar in the treatment of ventricular tachycardia.

(*Ann Thorac Surg* 1993;55:135-9)

There are numerous methods that are currently used for the surgical treatment of drug-refractory ventricular tachycardia. These include subendocardial resection [1-4], cryothermia [5-9], laser ablation [10, 11], left ventricular aneurysmectomy, and placement of antitachycardia/cardioverter/defibrillator devices [12, 13]. For patients in whom endocardial scar is suggested as the substrate for macroreentry for the initiation of ventricular tachycardia, subendocardial resection with cryosurgery has become the most popular open heart procedure. Although it has a relatively good success rate [2, 3, 14], the creation of cryolesions can be time-consuming and, due to their circular geometry, may leave gaps between lesions [15].

The Argon Beam Coagulator (ABC) (System 6000 Electrosurgical Generator; Birtcher Medical Systems, Inc, Irvine, CA) is a radiofrequency isolated electrosurgical generator [16]. It uses a coaxial, laminar flow of argon gas to enhance coagulation, which results in increased control and efficacy of coagulation. The device has a nozzle that must be held 1 cm or less above the tissue to be coagulated, and it may be moved in a "painting" motion over the desired area. The main advantages are that the ABC may be applied quickly, allows application to areas that may be difficult to reach using other techniques, and produces a visible lesion so as to prevent skip areas.

This system, in addition to subendocardial resection, has been used successfully at Duke University Hospital in 12 patients with medically refractory ventricular tachycardia to ablate endocardial scar tissue associated with ar-

rhythmogenesis. The purpose of this study was to characterize the lesions created by the coagulator and compare them with lesions produced by cryothermia.

Material and Methods

Ten adult dogs were anesthetized using pentobarbital (30 mg/kg), intubated, and ventilated using a Harvard respirator. All animals received humane care in compliance with the "Guide for the Care and Use of Laboratory Animals" published by the National Institutes of Health (NIH publication No. 85-23, revised 1985). An unperfused model was selected whereby a median sternotomy was performed and hearts were rapidly excised. The atria were removed and the right ventricle was dissected off the left ventricle and septum. The left ventricle was opened with an incision through the septum, and the endocardial surface was exposed completely to give a rectangular block of myocardium. In 5 animals, the ABC was used to create endocardial lesions. A template with ten openings, each measuring 1×1 cm, was placed over the endocardium. The ABC was used to create lesions by passing the hand piece and nozzle over the individual openings at a rate of approximately 1 cm/s. Several passes were made over the opening until the tissue was completely ablated. Several lesions were created at different power settings: 50, 75, 100, 125, and 150 W with either one or two complete applications to each block. Therefore, a total of 50 lesions were created.

In 5 other animals, cryolesions were created using hearts excised in the same fashion as above. A heating pad was placed under the myocardium and set at 37°C to act as a heat sink. The endocardial surface was used first

Application Frequency	Power Level (W)				
	50	75	100	125	150
1	2.25 ± 1.05	1.65 ± 0.05	2.36 ± 0.93	5.09 ± 0.64	6.64 ± 0.75
2	3.3 ± 1.6	3.83 ± 2.1	7.78 ± 2.1	11.03 ± 2.2	11.2 ± 1.1

^a Depth of lesion (mm) created by Argon Beam Coagulator at different power levels using either one or two applications performed at a rate of approximately 1 cm/s. (Mean ± standard error of the mean.)

to create lesions using a 15-mm cryoprobe (Frigitronics Inc, Shelton, CT). Several lesions were created by placing the probe on the heart and cooling to -70°C for either 1, 2, 3, or 4 minutes. The tissue was turned over to expose the epicardial surface, on which the cryoprobe was placed again for 1, 2, 3, or 4 minutes. Eight lesions were created for each heart for an overall total of 40.

Once the lesions were produced, the hearts were tacked onto cork boards and placed in 10% formalin solution. Once adequately fixed, the lesions were excised from the myocardial slabs and dehydrated through graded ethanols followed by embedding in paraffin on a Tissue-Tek VIP 3000 (Miles Scientific, IL) automatic embedding apparatus. Thin sections (6 μm) were cut on a microtome and stained with Verhoeff-van Gieson-Masson modified connective tissue stain. The sections were then assessed by light microscopy, and depths were measured using a computer-assisted image analysis system (Videometric System 150; Innovision, San Diego, CA).

Argon beam coagulator data were assessed using linear regression analysis (SAS Institute, Cary, NC). Cryolesions were compared at different times using analysis of variance. A *p* value of 0.05 was considered indicative of statistical significance.

Results

A total of 10 dogs weighing 24.85 ± 1.3 kg were used. In the ABC group, 5 hearts received 50 lesions, of which 39 were acceptable for histological examination. Eleven samples showed surface disruption as a result of fixation and preparation and therefore were not acceptable to measure lesion depths. The lesion depths for the different power outputs and frequency of passes are shown in Table 1. Figure 1 shows the increase in tissue penetration with increasing power and number of passes. Using linear regression, the depth of lesion created by ABC correlated directly with increasing power levels with an *r* value of 0.842 for the single-pass group and 0.82 for the double-pass hearts.

Light microscopy revealed that ABC lesions created using 50 and 75 W with one pass resulted in an intact superficial connective tissue layer consisting of elastic elements and collagen and a few cells along the endocardial surface. At power levels of 100 W and greater, there was a deeply eosinophilic, coagulated myocardial cellular change which increased in thickness with increasing power. All of the double-pass lesions showed dark-staining, carbonized, vacuolated connective tissue layers.

Myocardium had a thicker eosinophilic, coagulated cell layer with marked vacuolization, which was first evident in the 100-W power output lesion. Lesions were generally well-demarcated and circumscribed (Fig 2).

Five hearts were used for the cryolesions with 40 lesions created, of which 30 were useful for microscopic analysis. Rejection of samples was based on surface disruption, inability to determine lesion borders, and improper fixation of tissue. The heart was placed on a heating pad, but it was difficult to maintain constant temperature. Temperatures ranged from 32° to 37°C . The depth of the lesions at the midpoint of the ice ball for the different times of application are shown in Table 2. Analysis of variance revealed that there were no statistically significant differences between the depths of lesions for the different application times using either epicardial or endocardial lesions.

Histological examination showed that the cryolesions had intact surfaces with well-demarcated edges and homogeneous necrosis within the lesions (Fig 3). However, there were several lesions that were difficult to measure due to the application of the probe over an area of

Fig 1. Increasing depth of lesions created with the Argon Beam Coagulator as the power level is elevated. Lesions created with a single application are denoted by the circles; those from a double application are shown by the squares. (Mean ± standard error of the mean.)

Fig 2. Lesion created by the Argon Beam Coagulator at a power setting of 100 W with one application. (Magnification, $\times 6.5$ before 40% reduction.)

trabeculation on the endocardial surface. The trabecula would create pockets and bridges between it and the underlying myocardium, which would make it difficult for the cryoprobe to freeze the myocardium lying below the trabecula uniformly (Fig 4). This lack of uniformity was not seen in the ABC group, presumably because of the directed gas's ability to focus the heat below and around trabeculae.

Comment

In patients with medically refractory reentrant ventricular tachycardia, surgical treatment has proved to be effective. The most common procedures involve subendocardial resection and cryoablation of scar tissue with or without resection of a left ventricular aneurysm. Despite the variability of ventricular function and the substrate for and nature of the dysrhythmias, surgical results have been acceptable, with operative mortality varying between 10% and 20% [3, 14]. Success rates for ablating the dysrhythmias range from 70% to 93% [2, 3, 14].

The operations can often be long and complicated, especially if numerous mapping procedures are performed, a large area of subendocardial resection is required, or many cryolesions must be placed. Cryolesions take 2 to 3 minutes each with an average of 6 to 12 lesions

Fig 3. Lesion created by a 15-mm cryoprobe for 3 minutes on the endocardial surface. (Magnification, $\times 6.5$ before 12% reduction.)

required per case [6] (ie, 12 to 36 minutes). In addition, cryolesions are made usually with circular probes, requiring that lesions be overlapped 2.5 mm to assure complete

Fig 4. Another lesion created by a 15-mm cryoprobe for 3 minutes, which demonstrates the irregularity of the surface of the endocardium resulting in a variable depth of penetration by the cryoprobe. (Magnification, $\times 6.5$ before 22% reduction.)

Table 2. Cryolesion Depth^a

Site	Duration of Freeze (min)			
	1	2	3	4
Epicardium	6.10 $\pm$ 0.43	6.35 $\pm$ 1.31	6.92 $\pm$ 0.31	6.55 $\pm$ 1.28
Endocardium	7.88 $\pm$ 1.63	9.9 $\pm$ 1.52	7.7 $\pm$ 1.82	10.2 $\pm$ 2.65

^a Depth of lesion (mm) created by 15-mm cryoprobe for different times either on the epicardial or endocardial surface of the canine ventricle. (Mean $\pm$ standard error of the mean.)

coverage [15]. It is therefore possible to have areas where there is inadequate ablation, which may result in a substrate that would support recurrence of the dysrhythmia.

The ABC system uses radiofrequency energy to excite argon gas within a nozzle. The beam then exits the nozzle and spreads evenly over the tissue, heating it to a maximum of 110°C [16]. The excited gas can flow into channels and pockets created by the trabeculation of the ventricle, thereby enabling its application to be more uniform over an irregular surface. This type of ablation may be advantageous because it may be applied more rapidly than cryothermia, resulting in a visible color change of the tissue indicating that an area has been covered. The depth of penetration of the lesion varies depending on the power of the radiofrequency energy and duration of application as shown in this study. In addition, the created lesion appears to be homogeneous and well-circumscribed, which should not support further reentry. In the 12 patients who have received ABC treatment for their ventricular dysrhythmia, there have been no measured adverse effects on ventricular function.

The cryolesions created during this study show that lesion depth may be affected seriously if there are any irregularities of the surface of the endocardium. Most experimental studies assessing cryolesion depth have been performed using only epicardium, which has a smooth surface [15, 17]. Because there are often trabeculated areas of left ventricular endocardium that are cryoablated, this may be another reason for inadequate coverage in addition to failure to overlap lesions.

Previous studies have reported that cryolesion depth is affected by temperature of the tissue and duration of application. This was not well reproduced under our test conditions. In fact, lesions all had similar depths irrespective of duration of cryoablation. This likely reflects the fact that the tissue was not perfused during this study. The maximal cryolesion was created early during the application of the probe. Mikat and associates [18] showed that an average lesion depth of 5 mm was created when the cryoprobe was applied to the epicardium of perfused dog hearts for 90 to 120 seconds. This is less than the 9.9-mm lesion that was created during the same time under our experimental conditions. Perfused tissue likely creates a dynamic heat sink, and therefore it takes longer to create the maximal lesion. Other variables known to affect cryolesion depth are temperature and nitrous oxide tank pressure. Holman and colleagues [17] and Markovitz and co-workers [19] both showed that cryolesions had similar sizes when applied to tissues at 32° to 37°C but deepened as the temperature decreased. Despite maintenance of tissue temperature greater than 32°C using a heating pad in this study, there were no differences in lesion depths. This further suggests that tissue perfusion is an important consideration for the determination of cryolesion depth and not just tissue temperature alone. Long cryothermia sessions can deplete nitrous oxide reserves, resulting in lower tank pressure. At lower tank pressures, lesion volumes can be reduced by 41% [19]. Therefore, the lesion created by cryothermia can be affected by numerous factors.

Creation of endocardial lesions using the ABC system is not without potential problems. First, the movement of the nozzle is completely at the discretion of the operator. Therefore, to assure a reproducible lesion, a constant motion must be practiced. Because the device heats tissue, the operator must be especially careful near valves and chordae to prevent damage of these structures. However, an advantage is its extreme maneuverability and precision of application, which is in contrast to cryothermia. Although this was an acute study, the chronic lesion created by the device is likely to be similar, as has been reported by other groups using other ablation techniques [15, 17]. Unlike experiments using cryothermia [20], this study did not assess the electrical neutrality of the lesions created, but it could be extrapolated from other studies using radiofrequency energy that ablated tissue would be electrically silent after treatment. Although we did not compare the ABC lesions with those created by argon or neodymium:yttrium-aluminum garnet lasers [10, 11], we believe that the ABC system may be as effective as lasers.

This study used a nonperfused animal model for the creation of ABC and cryolesions. The advantages of this model are that it is simple, allows for a large number of lesions to be created per animal heart, and facilitates using endocardium or epicardium as substrate. Perfused models are limited by the number and location of lesions that may be produced and are much more cumbersome to perform. We believe that this model has resulted in the creation of lesions that are reproducible and similar to those produced using other models (with the exception of not being able to show a temperature/time dependence for cryolesions for reasons as outlined). In addition, observations with respect to endocardial cryolesions are important and should be considered when using this technique.

In conclusion, the ABC produces discrete, homogeneous, well-demarcated lesions, the depths of which are controllable by adjusting the power output of the device and the number and duration of applications. It may be a useful adjunct for the treatment of ventricular tachycardia when an open heart procedure is warranted.

Noncardiogenic Pulmonary Edema Complicating Lung Resection

David A. Waller, FRCS, Cengiz Gebitekin, MD, Nigel R. Saunders, FRCS, and Duncan R. Walker, FRCS

Department of Cardiothoracic Surgery, Killingbeck Hospital, Leeds, United Kingdom

Postresectional pulmonary edema is a rare but potentially fatal complication of thoracic operations. In a retrospective study of 402 lung resections we have identified 11 cases of postresectional, noncardiogenic pulmonary edema. We have analyzed the individual data to test recognized hypotheses regarding this condition. Pulmonary edema occurred in 5.1% of right pneumonectomies, 4.0% of left pneumonectomies, and 1% of all lobectomies. In 2 patients the symptoms occurred immediately after operation; in the other 9 the mean interval to diagnosis was 43.4 hours. All 11 patients were in a positive fluid balance in the first 24 hours after operation

(mean, 20.8 ± 9.1 mL/kg). However, there was no significant difference between this value and the respective values for control groups of 20 patients having pneumonectomies and 20 patients having lobectomies in whom pulmonary edema did not develop. Our findings differ from other reported series in that perioperative fluid overload was not found to be a significant contributory factor in the development of postresectional pulmonary edema. We discuss other possible mechanisms for this phenomenon.

(*Ann Thorac Surg* 1993;55:140-3)

Noncardiogenic pulmonary edema after lung resection is a rare but potentially life-threatening complication. Most thoracic surgeons are aware of anecdotal reports of this condition, but there have been few reviews of large series of patients [1, 2]. The underlying mechanism therefore remains undetermined, and explanations are based largely on animal experimental work [3]. At present noncardiogenic pulmonary edema is thought to comprise an increase in filtration pressure across the alveolar-capillary membrane with a decrease in the lymphatic drainage of the affected lung [1]. There is also evidence for increased permeability of the alveolar-capillary membrane [4]. Significant contributory factors that have been previously identified include the amount of lung tissue resected and a large perioperative fluid load [3]. However, we have observed this condition in patients who have received a comparatively small fluid load. We have therefore reviewed the data on patients who have undergone lung resection since 1983 and have analyzed the details of those in whom noncardiogenic pulmonary edema has developed. We aimed to test the recognized hypotheses regarding this rare condition.

Material and Methods

The records were reviewed of 402 patients who underwent lung resection at Killingbeck Hospital between 1983 and 1991. Pneumonectomy was performed in 205 (79 right

and 126 left), lobectomy in 155, bilobectomy in 30, and wedge resection in 12. Noncardiogenic pulmonary edema was diagnosed on clinical, radiological, or postmortem findings having excluded the following causes: cardiac failure due to myocardial infarction or cardiac arrhythmia, chest infection, aspiration pneumonia, pulmonary thromboembolism, and adult respiratory distress syndrome due to septicemia. Anesthetic and intensive care records were analyzed to calculate the intraoperative fluid load and the fluid balance for the immediate postoperative period. A figure for the net fluid balance in the first 24 hours after operation was derived from the intravenous colloid and crystalloid administration (including intraoperative), intraoperative blood loss (calculated from operating room suction and swab weight), urine output and nasogastric aspiration, and postoperative intercostal drainage. Differences between patients in whom pulmonary edema developed and those in whom it did not were assessed by the Mann-Whitney U test.

Results

Eleven cases of pulmonary edema complicating lung resection were identified (2.7% of all cases), occurring in 5 of 126 (4%) left pneumonectomies, in 4 of 79 (5.1%) right pneumonectomies, and in the contralateral lung in 2 of 197 (1%) lesser resections (155 lobectomies, 30 bilobectomies, and 12 wedge resections). Nine men (3.0% of all male patients) and 2 women (2%) aged 42 to 70 years (mean age, 57.0 ± 8.5 years) were affected. There was a history of cardiovascular disease in 3 patients. Mean preoperative pulmonary function test results were as follows: forced vital capacity, 3.4 ± 0.8 L, and forced expiratory volume in 1 second, 2.2 ± 0.6 L.

Accepted for publication May 6, 1992.

Table 1. Details of Survivors of Postresectional Pulmonary Edema

Patient No.	Sex	Age (y)	Operation	Interval to Symptoms
1	M	42	L pneumonectomy	72 h
2	M	56	L pneumonectomy	48 h
3	M	65	R upper lobectomy	72 h
4	M	63	R pneumonectomy	Immediate
5	M	48	L pneumonectomy	48 h

L = left; R = right.

The mean total intraoperative fluid load for this group was $1,555 \pm 668$ mL (mean colloid, 1,050 mL; mean crystalloid, 607 mL). All patients were in a positive fluid balance for the immediate 24-hour postoperative period (mean, 20.8 ± 9.1 mL/kg body weight). These results were compared with the respective values for two control groups. One group (18 male and 2 female patients; mean age, 62.6 ± 5.4 years) comprised the last 20 consecutive pneumonectomies (13 left, 7 right) performed in this unit. The second group (15 male and 5 female patients; mean age, 61.8 ± 7.0 years) comprised the last 20 consecutive lesser resections (6 right upper lobectomies, 5 left upper, 5 left lower, 3 bilobectomies, and 1 right lower) performed in this unit. One patient in each group had prior evidence of cardiovascular disease. The respective mean values for fluid balance in the immediate 24-hour postoperative period were 15.7 ± 6.4 mL/kg in the pneumonectomy group and 20.5 ± 10.8 mL/kg in the lobectomy group. Using the Mann-Whitney U test, these values were not found to be significantly different from those in patients in whom pulmonary edema developed ($p = 0.81$).

In 2 patients pulmonary edema was recognized immediately after the operation. In the remaining 9 patients the mean onset of symptoms was 43.4 ± 19.9 hours after operation.

Six patients subsequently died, despite mechanical ventilation in all 6 (mean duration, 6.3 ± 3.8 days) at a mean postoperative interval of 14.4 days. Further analysis of those who survived and those who died is presented in Tables 1 and 2. There was no difference between the groups in terms of type of resection, mean age (54.8 versus 58.8 years), mean interval to symptoms (48 ± 29

Table 2. Details of Deaths Caused by Postresectional Pulmonary Edema

Patient No.	Sex	Age (y)	Operation	Interval to Symptoms
1	M	70	R pneumonectomy	12 h
2	M	48	L pneumonectomy	48 h

versus 27 ± 21 hours), or cardiovascular disease (1 survivor, 2 who died).

Case Report:

The following case report illustrates the typical clinical findings in postresectional pulmonary edema. A 62-year-old businessman was admitted for right thoracotomy for squamous carcinoma of the bronchus. Preoperative investigations revealed no evidence of ischemic heart disease, and spirometry was good: forced vital capacity, 3.4 L; forced expiratory volume in 1 second, 2.6 L; ratio of forced vital capacity to forced expiratory volume in 1 second, 0.76.

At operation tumor was found to be impinging on the right main bronchus and there was no evidence of lymph node involvement. A standard right pneumonectomy was performed with staple closure of the right main bronchus. The operation lasted 3 hours. Intraoperative blood loss was approximately 500 mL, and fluid replacement during this period consisted of 1,000 mL of Hartmann's solution and 500 mL of hydroxyethyl starch.

The patient was extubated at the end of the procedure and began to breathe spontaneously. Within 30 minutes respiratory distress developed and he suffered a respiratory arrest. He required immediate endotracheal intubation and was transferred to the intensive care unit, where he was found to be in severe pulmonary edema (Fig 1) and severely hypoxic: oxygen tension, 6.67 kPa (50 mm Hg); carbon dioxide tension, 7.28 kPa (55 mm Hg). His peak inflation pressure was elevated at 49.6 cm H₂O, and he was fully ventilated on 60% oxygen.

A Swan-Ganz catheter was inserted, and pulmonary artery pressures were found to be elevated (systolic, 42 mm Hg; diastolic, 21 mm Hg), although the pulmonary capillary wedge pressure was low at 4 mm Hg. Cardiac output (measured by thermodilution) was 5.8 L/min.

A diuresis of 800 mL was induced over the next 6 hours by intermittent boluses of furosemide; pulmonary func-

tion and peak inflation pressures subsequently improved, but attempted extubation was unsuccessful. Continued diuresis was maintained and intravenous fluid administration was limited to 200 mL of salt-poor albumin per day. By the fourth postoperative day peak inflation pressures had fallen to normal, radiographic appearances were resolving, and extubation was successful.

The patient made an uneventful subsequent recovery and was discharged from the hospital 14 days after operation. Serial cardiac enzyme level determinations and electrocardiography revealed no evidence of a perioperative myocardial infarction. Microbial cultures from endotracheal secretions were negative.

Comment

Our findings differ from those of other reported series in that we have found that the development of pulmonary edema after lung resection does not appear to be associated with a significantly excessive perioperative fluid load. We found no significant difference between the perioperative fluid load administered to the patients in whom edema developed and those in whom it did not. The mean positive fluid balance in the first 24 hours after operation in our group in whom edema developed was also lower than that in other reported series [1, 2, 4, 5]. In all of these series fluid overload was thought to be a major cause of pulmonary edema.

Our series of patients differed in some other ways from those in other reports. Although it is rarely reported, we have documented the occurrence of pulmonary edema after lobectomy. Also, unlike other authors [1], we have not found that the side of pneumonectomy is a significant risk factor.

The mechanism of pulmonary edema after lung resection remains undetermined. Two underlying processes are believed to occur: raised capillary hydrostatic pressure and increased capillary permeability. After major lung resection the remaining lung tissue is subjected to an increased pulmonary artery blood flow as the cardiac output is redistributed [1]. As demonstrated in the case report presented here, the mean pulmonary artery pressure increases but the pulmonary capillary wedge pressure is not elevated owing to distention and recruitment of the pulmonary microvasculature and reduction in total pulmonary vascular resistance [6]. Pulmonary capillary wedge pressure may, however, be falsely low owing to a decrease in cardiac output on occlusion of the pulmonary artery caused by acute compromise of the reduced pulmonary vascular bed [7]. Fluid filtration is flow dependent [6], and as the mean capillary pressure rises, the net filtration force increases [1]. The formation of edema is also thought to be accelerated by the reduction in effective lymphatic drainage by lung resection [3]. Perioperative fluid overload compounds the problem by further increasing cardiac output, pulmonary artery pressure, and net filtration.

Evidence for an increase in permeability in postresection edema comes from a report of 5 patients in whom endotracheal aspirates demonstrated an elevated edema fluid: serum protein ratio [4]. There were methodological

problems in that the aspirates may have been contaminated by upper airways secretions, but other evidence exists to favor a change in permeability. Experimental work with isolated perfused dog lobes has demonstrated a disproportionate increase in edema formation with elevated pulmonary venous pressures [8]. This had been previously attributed to a decrease in tissue buffering as the lung became more edematous, but these experiments showed this phenomenon to be independent of tissue hydration. A more likely explanation is that permeability is increased by pressure effects on the alveolar-capillary membrane. There is further experimental evidence that distention may widen the intercellular junctions within the endothelial layer of the alveolar-capillary membrane, facilitating fluid efflux [9]. There is also evidence that the high resistance of the alveolar epithelium (which is up to 10 times less permeable than the endothelium) may suddenly break down under mechanical stress, ie, fluid distention [10, 11].

Why pulmonary edema develops in some patients after lung resection despite relatively little fluid load and comparatively little reduction in effective lymphatic drainage (ie, after lobectomy) remains unknown. However, the underlying mechanism may be damage to the alveolar-capillary membrane. A transient increase in postoperative pulmonary capillary pressure, which is already elevated, may be sufficient to widen or damage intercellular junctions, causing subsequent fluid efflux. Possible causes of a sudden increase in pressure include release of endogenous catecholamines in response to pain and reflex pulmonary vasoconstriction in response to transient hypoxia.

Further study into the mechanism of pulmonary edema after lung resection is clearly required. It is not satisfactory to attribute the effects to perioperative fluid overload alone. Investigations into the changes in permeability of the alveolar-capillary membrane during and after lung resection should be performed.

We thank Mr N. R. Saunders and Mr D. R. Walker, Consultant Cardiothoracic Surgeons, for their permission to report their cases.

Notice From the American Board of Thoracic Surgery

The American Board of Thoracic Surgery began its recertification process in 1984. Diplomates interested in participating in this examination should maintain a documented list of the operations they performed during the year prior to application for recertification. This practice review should consist of 1 year's consecutive major operative experiences. (If more than 100 cases occur in 1 year, only 100 need to be listed.) They should also keep a record of their attendance at approved postgraduate medical education activities for the 2 years prior to application. A minimum of 100 hours of approved CME activity is required.

In place of a cognitive examination, candidates for recertification will be required to complete both the general thoracic and cardiac portions of the SESATS IV syllabus (Self-Education/Self-Assessment in Thoracic Surgery). It is not necessary for candidates to purchase

SESATS IV booklets prior to applying for recertification. SESATS IV booklets will be forwarded to candidates after their applications have been accepted.

Diplomates whose 10-year certificates will expire in 1995 may begin the recertification process in 1993. This new certificate will be dated 10 years from the time of expiration of the original certificate. Recertification is also open to any diplomate with an unlimited certificate and will in no way affect the validity of the original certificate.

The deadline for submission of applications is May 1, 1993. A recertification brochure outlining the rules and requirements for recertification in thoracic surgery is available upon request from the American Board of Thoracic Surgery, One Rotary Center, Suite 803, Evanston, IL 60201.

Comparison of Two Experimental Models for Assessment of Cardiac Preservation

Stephen E. Fremes, MD, Robert D. Furukawa, BSc, Ren-Ke Li, MD,
Richard D. Weisel, MD, Donald A. G. Mickle, MD, and Laura C. Tumati, BSc

Divisions of Cardiovascular Surgery and Clinical Biochemistry, Center for Cardiovascular Research, University of Toronto, Toronto, Ontario, Canada

Previous studies from this institution using human cell cultures have suggested that University of Wisconsin solution is preferred for prolonged hypothermic storage for cardiac transplantation. The primary objective of this study was to evaluate the effectiveness of extended cardiac preservation with University of Wisconsin solution by assessing the time-related changes of purine metabolites using two different models of cold storage. Isolated rat hearts ($n = 6/\text{group}$) or human ventricular myocyte cultures ($n = 7$ dishes/group) were assessed after 0, 6, 12, and 24 hours in University of Wisconsin solution at 0°C using high-performance liquid chromatography. Adenosine triphosphate content decreased from 18.1 ± 5.4 to $9.6 \pm 2.7 \mu\text{mol/g}$ dried weight by 12 hours and to $1.0 \pm 0.6 \mu\text{mol/g}$ by 24 hours ($p < 0.0001$ by analysis of variance) in the rat model. Adenosine triphosphate content decreased from 0.64 ± 0.42 to 0.14 ± 0.11

$\text{nmol}/\mu\text{g}$ DNA at 6 hours and to $0.04 \pm 0.03 \text{ nmol}/\mu\text{g}$ DNA by 24 hours ($p < 0.00001$) in the cardiomyocytes. Inosine monophosphate content increased from 0.1 ± 0.2 to 10.8 ± 1.0 by 24 hours ($p < 0.0001$) in the rat studies. Inosine monophosphate values tended to increase up to 12 hours ($p = 0.06$) in the cell cultures and then declined. Adenosine concentration increased from 0.3 ± 0.3 to $2.3 \pm 0.9 \mu\text{mol/g}$ at 6 hours and declined thereafter ($p < 0.0005$) in the rodent hearts. Adenosine concentration increased from 0.03 ± 0.02 to $1.53 \pm 0.72 \text{ nmol}/\mu\text{g}$ DNA at 6 hours ($p < 0.0001$) in the cardiomyocytes. Human cell cultures may represent a more sensitive model to evaluate adenine nucleotides after cardiac storage conditions and avoid species-specific changes in purine degradation. Nucleoside contents are likely increased unphysiologically with this experimental technique.

(*Ann Thorac Surg* 1993;55:144–50)

University of Wisconsin solution (UWS) at 0°C may be the preferred storage conditions for cardiac transplantation according to results from our laboratory [1–3] and others [4–10] and recent clinical trials [11, 12]. Previous studies from this institution investigated human cardiomyocytes as a screening model of organ preservation. Despite the potential advantages of using human cell cultures for evaluation of storage techniques [13], this methodology represents a substantial departure from the intact organ. Whole organ preservation with UWS at 0°C has been evaluated in these current studies, and the results compared with the findings obtained using human cardiomyocytes.

Material and Methods

Rat Protocol

Hearts were obtained from Sprague-Dawley rats (250 to 500 g). All animals received humane care in compliance with the "Guide for the Care and Use of Laboratory Animals" (NIH publication No. 85-23, revised 1985). Animals were anesthetized with an intraperitoneal injection of sodium pentobarbital. A median sternotomy was then performed, and the hearts were rapidly excised and

submerged in chilled normal saline solution. Control hearts were immediately immersed in liquid nitrogen after cardiac arrest (0 hours, $n = 6$). Experimental hearts were flushed with UWS, 15 mL/kg body weight, over a 2-minute interval. The hearts were subsequently stored at 0°C for 6, 12, or 24 hours ($n = 6/\text{group}$) in 15 to 20 mL of chilled UWS.

After the storage interval, the hearts were immersed in liquid nitrogen and then lyophilized. Tissue was homogenized on ice with 0.5 mol/L perchloric acid. Samples were centrifuged at 2,500 rpm for 10 minutes, and the supernatant was neutralized with 2 mol/L potassium hydroxide to a pH of 7.6 and reacidified with 0.1 mol/L perchloric acid to a pH of 6.8. Samples were frozen in liquid nitrogen, lyophilized, and stored at -80°C until reconstitution in 100 mmol/L $\text{NH}_4\text{H}_2\text{PO}_4$ buffer before analysis using high-performance liquid chromatography.

Cell Culture Protocol

Ventricular myocardium was obtained during elective repair of Tetralogy of Fallot from patients who had signed a consent form approved by the institutional human ethics committee. Human cardiomyocyte cultures were prepared as previously described with slight modifications [1–3]. Tissue was minced, after which the cells were dissipated with collagenase (0.1%) and trypsin (2%). The supernatant was collected. Cells were separated by centrifugation for 5 minutes at 2,000 rpm. The precipitated

Accepted for publication May 12, 1992.

Fig 1. The results (mean $\pm$ standard deviation) of adenosine triphosphate (ATP), adenosine diphosphate (ADP), and adenosine monophosphate (AMP) levels in rodent hearts ($n = 6/\text{group}$) are displayed. Data are presented for control samples (0 hours) and after 6, 12, and 24 hours of hypothermic storage with University of Wisconsin solution. Probability values are presented for analysis of variance (ANOVA) where significant, and differences between means are specified with a multiple-comparison t test. The level of ATP had decreased by 6 hours and ADP after 24 hours, whereas no significant change occurred for AMP.

cells were suspended in culture medium containing 10% fetal bovine serum and Iscove's modified Dulbecco's medium (Gibco Laboratories Life Technologies Inc, Grand Island, NY) with 1% penicillin-streptomycin at 37°C with an environment of 5% CO_2 and an oxygen tension of 150 mm Hg.

Cells were grown until confluent, and then passage with trypsin performed. Fibroblasts and myocytes were manually separated and the identity of the myocytes verified using anti-actin [14] and anti-ventricular light chain 1 antibodies [15]. Experiments were performed using nonconfluent dishes ($n = 7/\text{group}$).

For the control studies (0 hours), the culture media was discarded and the cells were rinsed with chilled phosphate-buffered saline solution and then frozen with liquid nitrogen. For the experimental groups, the culture media was discarded and the cells were rinsed with phosphate-buffered saline solution. Ten milliliters of chilled UWS was then added to each dish. Cells were stored at 0°C for 1, 6, 12, or 24 hours.

After the preservation period, the storage fluid was discarded and the cells were rinsed with phosphate-buffered saline solution and then frozen with liquid nitrogen. The tissue was lyophilized and stored at -80°C. Nucleotides were extracted from myocytes based on a methodology described by Shryock and associates [16] as previously described.

The protocol for DNA quantification was based on the

method of Maniatis and colleagues [17]. The samples were assayed on a Beckman DU-40 spectrophotometer (Beckman Instruments Inc, Irvine, CA) at 260 nm.

Measurements

The levels of adenine nucleotides and their degradation products were measured using high-performance liquid chromatography according to a modification of the method of Hull-Ryde and associates [18] and employing the Waters Maxima 820 Chromatography Workstation computer program as previously described [3, 19]. Samples were maintained at 4°C and injected with an automatic injector (model 700 Satellite WISP; Waters Associates, Mississauga, ON, Canada). A step-gradient solvent delivery was accomplished via a Waters Solvent Select Valve and two reciprocating pumps (Waters Associates, models 501 and 510). The chromatographic column was a Radial-Pak Resolve C18 column with a 5- μm particle size (Waters Associates), which was operated in a radial compression module (Waters Associates, model RCM 8 $\times$ 10) at 175 kg/cm^2 . A programmable multiwave length detector (Waters Associates, model 490) was used to monitor the peaks. The previously mentioned equipment was controlled by a System Interface module (Waters Associates, model I-200). The system measured the levels of uric acid, adenosine triphosphate (ATP), inosine monophosphate, adenosine diphosphate (ADP), hypoxanthine, xanthine, adenosine monophosphate (AMP), inosine, adenosine, and 2'-O-methyladenosine (internal standard) at 254 nm. Peak areas were integrated by the Waters Maxima 820 computer program. The concentrations of the adenine nucleotides and their degradation products were expressed as micromoles per gram of freeze-dried weight for the rat studies and nanomoles per microgram of DNA for the cell culture studies.

Statistical Analysis

Data analysis was facilitated using Statistical Analysis System software (SAS Institute, Cary, NC) and a microcomputer. Data are summarized as the mean $\pm$ standard deviation in the text and figures. The treatment effect due to time within each group was tested initially using a one-way analysis of variance, and the differences between means were specified with Duncan's multiple range test [20]. A comparison of isolated organ and cell culture experiments was performed using percentage transformed data and two-way analysis of variance. Comparisons were performed initially with a percentage transformation of the data assuming the 0-hour mean values represent 100% and secondly expressing the data as a percentage of the mean 0 hour sum of all purine compounds. Statistical significance is assumed for p values less than 0.05.

Results

Part I

The results of the rat studies for ATP, ADP, and AMP are summarized in Figure 1. The level of ATP decreased from

Fig 2. The results (mean $\pm$ standard deviation) of inosine monophosphate (IMP), adenosine, inosine, and hypoxanthine levels in rodent hearts ($n = 6/\text{group}$) are displayed. Data are presented for control samples (0 hours) and after 6, 12, and 24 hours of hypothermic storage with University of Wisconsin solution. Probability values are presented for analysis of variance (ANOVA) where significant, and differences between means are specified with a multiple-comparison t test. Inosine monophosphate was the most prominent degradation product identified following storage in the rodent heart.

18.1 $\pm$ 5.4 to 9.6 $\pm$ 12.7 $\mu\text{mol/g}$ by 12 hours. The level of ADP was maintained until 12 hours. Levels of ATP and ADP were severely depleted at 24 hours. The AMP concentration did not change significantly.

The serial changes of degradation products are depicted in Figure 2. Inosine monophosphate concentration increased from 0.1 $\pm$ 0.2 to 10.7 $\pm$ 1.0 $\mu\text{mol/g}$ at 24 hours. Adenosine level increased from 0.3 $\pm$ 0.3 to 2.3 $\pm$ 0.9 $\mu\text{mol/g}$ by 6 hours but decreased progressively subsequently. Both inosine and hypoxanthine concentrations increased progressively (inosine: 0 hour = 0.9 $\pm$ 0.5, 24 hour = 4.2 $\pm$ 0.3 $\mu\text{mol/g}$; hypoxanthine: 0 hour = 0.1 $\pm$ 0.1, 24 hours = 0.7 $\pm$ 0.2 $\mu\text{mol/g}$; $p < 0.0001$). The levels of xanthine and uric acid were always small (Table 1).

The proportional contribution of each of the purine metabolites is depicted in Figure 3. The total concentra-

Fig 3. The proportional contributions of each of the purine metabolites are presented for the rat heart studies ($n = 6/\text{group}$). Probability values are given for analysis of variance (ANOVA), and differences between means are specified with a multiple-comparison t test. Total measured purine compounds had increased at 6 and 12 hours but had decreased by 24 hours. (ADP = adenosine diphosphate; AMP = adenosine monophosphate; ATP = adenosine triphosphate; IMP = inosine monophosphate.)

tion increased from 33.4 $\pm$ 3.6 to 39.6 $\pm$ 1.9 $\mu\text{mol/g}$ by 6 hours but had decreased to 27.0 $\pm$ 2.6 $\mu\text{mol/g}$ by 24 hours.

Part II

The results of ATP, ADP, and AMP levels for the cell culture experiments are summarized in Figure 4. The level of ATP decreased from 0.64 $\pm$ 0.42 to 0.14 $\pm$ 0.11 nmol/ μg DNA by 6 hours and to 0.04 $\pm$ 0.03 nmol/ μg DNA by 24 hours. The levels of ADP and AMP both declined similarly.

The serial changes in degradation products are displayed in Figure 5. Inosine monophosphate values increased by 12 hours but declined subsequently ($p = 0.06$). Adenosine concentration increased from 0.03 $\pm$ 0.02 to 1.53 $\pm$ 0.72 nmol/ μg DNA at 6 hours, inosine concentration increased from 0.04 $\pm$ 0.04 to 0.74 $\pm$ 0.42 nmol/ μg DNA at 6 hours, and hypoxanthine concentration increased from 0.01 $\pm$ 0.01 to 0.13 $\pm$ 0.07 nmol/ μg DNA at 6 hours. Adenosine, inosine, and hypoxanthine levels each remained increased. The values of xanthine and uric acid were generally unmeasurable in the cell culture studies.

Table 1. Xanthine and Uric Acid in Rat Hearts ($n = 6$ hearts/group)

Variable	Time (hours)				p Value (ANOVA)
	0	6	12	24

ANOVA = analysis of variance; NS = not significant.

Fig 4. The results (mean $\pm$ standard deviation) of adenosine triphosphate (ATP), adenosine diphosphate (ADP), and adenosine monophosphate (AMP) levels in human cell cultures ($n = 7$ dishes/group) are displayed. Data are presented for control samples (0 hours) and after 6, 12, and 24 hours of hypothermic storage with University of Wisconsin solution. Probability values are presented for analysis of variance (ANOVA) where significant, and differences between means are specified with a multiple-comparison t test. The level of each of the nucleotides had declined significantly by 6 hours in the human cell experiments.

The proportional contribution of each of the purine metabolites is depicted in Figure 6. The total value increased from 1.0 ± 0.7 to a maximum of 3.3 ± 0.6 nmol/ μ g DNA at 12 hours, largely secondary to adenosine and inosine.

Part III

A quantitative comparison of the rat and human storage data is presented in Tables 2 and 3. The data are reported as percentages of the mean 0-hour values in Table 2. The data are reported as percentages of the mean 0-hour total purine values in Table 3 (ie, relative to $33.4 \mu\text{mol/g}$ for rat results and $1.0 \text{ nmol}/\mu\text{g}$ for human results). The p values associated with the F test for either the main effect (rat versus human) or interaction [time $\times$ (rat versus human)] are presented. Levels of ATP, ADP, and AMP are severely depleted more rapidly in the human than in the rat experiments. Inosine monophosphate is a more important degradation product in the rat studies than in the human. Adenosine, inosine, and hypoxanthine levels increase to a greater extent in the human compared with the rat preservations. Xanthine and uric acid values are small in both studies, but tended to be higher in the rat experiments.

Comment

Previous studies from this institution have assessed prolonged hypothermic storage using human cell cultures as

a screening model [1-3]. These studies indicated that UWS was preferred to Stanford cardioplegia, modified Euro-Collins, or phosphate-buffered saline solution. Other findings were that endothelial cells were, in general, more tolerant to cold storage than ventricular myocytes and that preservation was enhanced with progressive temperature reduction [2]. We selected the 6-hour storage time to represent the current upper limit of tolerable ischemic time for cardiac transplantation, although experimental preparations have variable success after 12 to 24 hours [21, 22].

Isolated cell cultures provide an excellent model for metabolic investigations of myocardial tissue [13]. Human tissue is employed for these studies, eliminating concerns relative to species differences. Different tissues can be analyzed separately, for example, endothelial cell and cardiomyocytes. Despite the potential advantages of using cell cultures, this method represents a substantial departure from the intact organ. We therefore wished to compare results obtained using this technique with similar protocols and end points using an intact organ. Statistical comparisons were conducted with percentage transformed data to eliminate the differences in units for the rat heart and human cell experiments. A two-way analysis of variance was performed and results reported for the main

Fig 5. The results (mean $\pm$ standard deviation) of inosine monophosphate (IMP), adenosine, inosine, and hypoxanthine levels in human cell cultures ($n = 7$ dishes/group) are displayed. Data are presented for control samples (0 hours) and after 6, 12, and 24 hours of hypothermic storage with University of Wisconsin solution. Probability values are presented for analysis of variance (ANOVA) where significant, and differences between means are specified with a multiple-comparison t test. Pronounced elevations of adenosine and inosine levels were identified. This likely reflects diffusion of adenosine contained in University of Wisconsin solution into the myocyte and subsequent deamination.

effect (rat versus human) or interaction [time $\times$ (rat versus human)].

Qualitatively, the results of the two models are similar in many respects. Levels of adenine nucleotides decline, whereas levels of inosine monophosphate, adenosine, inosine, and hypoxanthine increase and those of xanthine and uric acid tend to decrease. Quantitatively, severe differences do exist between these two models in terms of the magnitude or rate of change from initial values or in terms of the proportional contribution relative to the total purine content. Some of these differences could be secondary to the differences in whole heart versus isolated cell, whereas others may be species-dependent.

Adenosine triphosphate concentration decreased to less than 25% of control values in the cell culture studies by 6 hours in association with significant depression of ADP and AMP values. This contrasted with a milder depression of the rodent ATP values, maintenance of ADP values, and increase in AMP values. Whole heart ATP levels after medium-term storage are generally well preserved in other experimental protocols [4, 8, 10] with UWS, consistent with the data from our studies. Human cell cultures appear to be a more sensitive model to assess interventions involving adenine nucleotides.

Fig 6. The proportional contributions of each of the purine metabolites are presented for the cell culture studies ($n = 7$ dishes/group). Probability values are given for analysis of variance (ANOVA), and differences between means are specified with a multiple-comparison t test. The sum of metabolites had increased by 6 hours, largely due to the contributions of adenosine and inosine. (ADP = adenosine diphosphate; AMP = adenosine monophosphate; ATP = adenosine triphosphate; IMP = inosine monophosphate.)

* Main effect refers to the (rat versus human) effect. Interaction refers to the [time × (rat versus human)] effect. ^b p < 0.05 versus rat value.

Inosine monophosphate levels increased to a much greater extent in the present rodent experiments than in the cell culture studies. Previous biopsy studies performed in coronary bypass patients undergoing elective revascularization procedures similarly identified only small quantities of inosine monophosphate in human myocardium [19]. This suggests that AMP is largely metabolized through adenosine in human myocardium whereas AMP-inosine monophosphate conversion is a more important pathway in the rat heart. Studies assessing the cardioprotective effects of adenosine supplementation [23-25] or blockers of adenosine metabolism [26, 27] may not be adequately evaluated using a species less dependent on AMP-adenosine conversion.

We have previously reported that human tissue levels of xanthine and uric acid were very small in isolated cardiomyocyte cultures [3] or left ventricular biopsy specimens after cardioplegic arrest [19]. Other investigators suggest that xanthine oxidase activity is minimal in human myocardium, although this remains controversial. It is probable that the differences in inosine monophosphate, xanthine, and uric acid levels are species-dependent.

The level of adenosine (and inosine after deamination)

increased to a greater extent in the human compared with rodent experiments. The concentration of total purine compounds increased threefold in the cell culture studies, largely secondary to the increase of adenosine and inosine (see Fig 6). Adenosine is present in UWS in a concentration of 5 mmol/L. As the isolated cardiomyocytes are submerged in a relatively large volume of storage solution during preservation, it is anticipated that diffusion of the permeable adenosine would be greater in the cell culture experiments, compared with the isolated rat heart, where diffusion is limited. The level of adenosine increased to 8.62 ± 1.18 nmol/mg protein in studies performed by Yeh and associates [5] using isolated rodent hearts. It is probable that the differences in adenosine and inosine concentrations represent model effects.

We have conducted long-term cardiac storage experiments with UWS using isolated rat heart and human cultured cardiomyocytes. Preservation for 24 hours is unsatisfactory, whereas limited protection is provided for 6 to 12 hours. Adenine nucleotides are depleted more rapidly in the cell culture studies. Inosine monophosphate (and, to a lesser degree, xanthine and uric acid) accumulates to a greater degree in the rat heart experiments, which likely represents a species-specific finding.

Adenosine and inosine levels increase more in the isolated cells, which probably is model-dependent.

Supported in part by an Ontario Heart and Stroke Foundation grant.

We wish to extend our gratitude to Mara Bajc and Zahir Hussain for assistance in preparation of the manuscript and Lisa Keaney for the artwork. We also wish to acknowledge our appreciation to the Multiple Organ Retrieval and Exchange Program for donation of the University of Wisconsin solution employed in these studies.

Distal Aortic Arch Aneurysmectomy and Coronary Revascularization Through a Left Thoracotomy

Shinichi Takamoto, MD, Takaaki Matsuda, MD, Mikio Harada, MD, and Yukio Shimamura, MD

Division of Cardiovascular Surgery, Showa General Hospital, Tokyo, Japan

A successful single operation of a distal aortic arch aneurysm and coronary artery disease through a left lateral thoracotomy using a simple hypothermic retrograde cerebral perfusion technique for cerebral protection in a 64-year-old man is reported. During ventricular fibrillation accompanying cooling to 15°C, a left internal

thoracic artery was anastomosed with the left anterior descending coronary artery, and the aneurysm was replaced with a patch during hypothermic retrograde cerebral perfusion.

(*Ann Thorac Surg* 1993;55:151-2)

Aortic aneurysm is often associated with coronary artery disease. Replacement of the ascending aorta and the aortic arch with coronary artery bypass grafting through a median sternotomy has been reported [1]; here we report replacement of the distal aortic arch with coronary artery bypass grafting through a left lateral thoracotomy.

We have recently reported that hypothermic cerebral retrograde perfusion can be achieved by simply elevating the central venous pressure in Trendelenburg position when the aortic arch is open [2]. During profound hypothermic perfusion of the lower half of the body with the descending aorta occluded, venous blood rich in oxygen supplied this oxygen to the brain, protecting it over a long period of cerebral circulatory arrest. Because this technique simplifies the operation, eliminating dissection of the arch vessels and the other special preparatory procedures, it can be used not only for a median approach but also for a lateral thoracotomy approach, which is suitable for operation on a distal aortic arch aneurysm.

We have performed distal aortic arch aneurysmectomy by this simple hypothermic method immediately after carrying out coronary artery bypass grafting using the left internal thoracic artery during the cooling process.

A 64-year-old man with a saccular type of distal aortic arch aneurysm had three-vessel coronary heart disease (No. 1, 100%; No. 6, 75%; No. 11, 99%) without angina or serious changes in the electrocardiogram. He had been suffering from systemic arteriosclerotic diseases such as old cerebral infarction with right hemiparesis, abdominal aortic aneurysm, and arteriosclerosis obliterans with occlusion of the right iliac artery.

Operation was performed through a left lateral thoracotomy (Fig 1). The left internal thoracic artery was dissected. The left femoral vein was cannulated to provide drainage of the right atrium, and the descending aorta was cannulated because of the difficulty of perfusion through the femoral artery. The left ventricle was vented through the apex. Cooling was initiated using regular cardiopulmonary bypass. During the ventricular fibrillation that accompanied cooling to 15°C, a left internal thoracic artery graft was anastomosed with the left anterior descending coronary artery. We also attempted to anastomose a saphenous vein graft to the posterior descending branch of the right coronary artery, but this graft was abandoned because dissection had occurred in this branch. The small left circumflex artery and the good collateral flow from the left anterior coronary artery to the right coronary artery offered assurance for the success of single bypass grafting.

After the rectal temperature reached 15°C, the descending aorta was clamped proximal to the cannulation site and cardiopulmonary bypass flow was reduced to 1,500 mL/min, 1 L/min/m². The patient was then placed in a mild Trendelenburg position, and the central venous pressure was raised to 15 mm Hg, slightly occluding the venous line of the pump. An incision was made in the aortic arch without clamping the arch vessels, and an aortic irrigation occlusion catheter was introduced into the ascending aorta through this incision for crystalloid cardioplegia and for blocking the blood flow from the left ventricle.

During retrograde cerebral perfusion carried out to supply oxygen to the brain, the saccular aortic arch aneurysm was replaced by a patch. After the descending aorta was declamped, the cardiopulmonary bypass flow was raised to the normal flow rate, and rewarming was initiated. In this period, cerebral and coronary reperfusion was commenced. The remainder of the operation was completed in the usual manner. Operation time was 587

Accepted for publication March 23, 1992.

Fig 1. Diagram of the operative procedure of a single operation for distal aortic arch aneurysmectomy with coronary artery bypass grafting through a left lateral thoracotomy. (AAA = abdominal aortic aneurysm; CABG = coronary artery bypass grafting; CPB = cardiopulmonary bypass; CVP = central venous pressure; LITA = left internal thoracic artery; LV = left ventricular; Vf = ventricular fibrillation.)

minutes, cardiopulmonary bypass time 238 minutes, cardiac and cerebral arrest time 70 minutes.

During hypothermic retrograde cerebral perfusion, substantial extraction of oxygen and lactate was noted in the brain. In the venous blood entering the cardiopulmonary bypass, the oxygen tension was 89 mm Hg, oxygen saturation was 96.4%, and the lactate level was 4.1 mmol/L (37.3 mg/dL). The retrograde perfusion blood in the carotid artery had an oxygen tension of 45 mm Hg, oxygen saturation of 71.4%, and a lactate level of 3.8 mmol/L (34.0 mg/dL). These data indicated substantial amounts of oxygen and lactate were extracted by the brain even in profound hypothermia.

The postoperative course of this patient was uneventful. There were no signs of neurologic or myocardial damages. Postoperative coronary angiogram revealed the patent graft. Abdominal aortic aneurysmectomy with a Y-shaped graft was successfully performed 6 months later through a retroperitoneal approach.

Comment

Retrograde cerebral perfusion performed under profound hypothermia by elevation of the central venous pressure is very simple, and requires neither special handling or dissection of the arch vessels, vena cava, and the ascending aorta nor any special bypass circuits. It can be used for a lateral thoracotomy using femoral vein drainage and aortic root perfusion by means of an irrigation occlusion catheter introduced through an incision at the site of an aneurysm.

Coronary artery bypass grafting through a lateral thoracotomy has been reported mainly for coronary reoperations [3-5]. Coronary artery disease associated with a

distal aortic arch aneurysm or a descending aortic aneurysm has generally been treated by earlier coronary artery bypass grafting or percutaneous transluminal coronary angioplasty [1]. The present one-stage operation had the advantages of reducing the physical and economic costs of two separate cardiopulmonary bypass operations, and of providing more adequate myocardial revascularization than balloon angioplasty. With this technique coronary artery bypass grafting can be carried out during cooling to deep hypothermia without substantial extension of the operation time, the internal thoracic artery is more easily dissected than through a median sternotomy, and the descending aorta can, if necessary, be selected as the cannulation site for cardiopulmonary bypass.

We are grateful to Mr Chris W. Reynolds for English correction of the manuscript.

Extracorporeal Membrane Oxygenation for Severe Heart Failure After Fontan Operation

Akira Saito, MD, Haruo Miyamura, MD, Hiroshi Kanazawa, MD, Hajime Ohzeki, MD, and Shoji Eguchi, MD

Department of Thoracic and Cardiovascular Surgery, Niigata University School of Medicine, Niigata, Japan

A 10-year-old boy with tricuspid atresia and Glenn anastomosis underwent a modified Fontan operation. After the operation, the pressure in the inferior vena cava increased, leading to oliguria and ascites. After the creation of continuity between the superior vena cava and the inferior vena cava to reduce the pressure gradi-

ent, there remained an elevated right atrial pressure. Six days of extracorporeal membrane oxygenation effectively stabilized his hemodynamics and organ function and allowed an excellent outcome.

(*Ann Thorac Surg* 1993;55:153-5)

The Fontan-type operation was developed to treat tricuspid atresia [1, 2]. Operative mortality and long-term survival are acceptable [3], but persistently elevated right atrial pressure (RAP) postoperatively sometimes causes renal failure, ascites, or hepatic failure. This condition is refractory to medical management, and extracorporeal membrane oxygenation (ECMO) is the most effective treatment presently available. We report a patient with tricuspid atresia successfully treated with ECMO for elevated RAP after a modified Fontan operation.

A 10-year-old boy with tricuspid atresia was admitted to our hospital for a corrective operation. He had visceral and atrial situs solitus, and the ventriculoarterial connections were normal. A large atrial septal defect, a muscular ventricular septal defect, a rudimentary right ventricle, and pulmonary valve stenosis were present. He had undergone a left Blalock-Taussig shunt and Glenn anastomosis previously. His weight was 31.8 kg, his height was 142 cm, and generalized cyanosis was noted on admission. Hematologic examination showed polycythemia (hematocrit, 0.59), and electrocardiography indicated left-axis deviation and left ventricular hypertrophy. Angiography revealed a widely patent Glenn anastomosis and an occluded left Blalock-Taussig shunt (Fig 1).

We performed a modified Fontan operation using a technique based on the method of Björk and associates [2]. Cardiopulmonary bypass was instituted, and a U-shaped incision was made in the right atrial appendage. The atrial septal defect was closed with an equine pericardial patch, and the main pulmonary artery (PA) was incised longitudinally to the anterior wall of the hypoplastic right ventricle. The ventricular septal defect was closed by direct suture, and the "floor" of the conduit, which had been created by the right atrial appendage, was

sutured to the everted right edge of the ventriculotomy. The anterior aspect of the atrioventricular communication was covered by an equine pericardial "roof," which was extended onto the main PA. At this point, blood flow from the superior vena cava drained into the right PA through the Glenn shunt, and flow from the inferior vena cava (IVC) drained into the left PA through the right atrium and right ventricle.

The postoperative course was uneventful until postoperative day 4, when oliguria and ascites developed. The IVC pressure was 23 mm Hg, which was 8 mm Hg greater than in the superior vena cava. Diuretics and catecholamines were ineffective, and we decided to reduce the IVC pressure surgically to improve perfusion of the abdominal organs. We created an anastomosis between the right atrium and the left brachiocephalic vein using a ringed expanded polytetrafluoroethylene graft (Gore-Tex; W.L. Gore & Assoc, Flagstaff, AZ; 12 mm in diameter). The pressure in the IVC, right atrium, and superior vena cava was 20 mm Hg after the anastomosis was opened.

The next morning, the RAP exceeded 25 mm Hg, and low cardiac output syndrome developed (Fig 2). Renal and liver function deteriorated, and we believed that multiorgan failure was inevitable without heroic intervention. We decided to initiate ECMO to reduce IVC pressure and increase cardiac output. The circuit was constructed using a 24F venous cannula, a roller pump, a silicone hollow fiber oxygenator (Merasilox; Senko Medical Instrument, Tokyo, Japan), and a 12F arterial cannula. The venous cannula was placed in the right femoral vein, and the arterial cannula was placed in the right femoral artery through an artificial graft (Gore-Tex). Extracorporeal membrane oxygenation was started at a flow rate of 1.5 L/min. Hemodynamics stabilized immediately, and the RAP decreased to less than 18 mm Hg. Heparin and nafamostat mesilate (a protease inhibitor) were administered to prevent coagulation, and the activated coagulation time was maintained at approximately 200 seconds. The extracorporeal continuous ultrafiltration method was

Accepted for publication March 27, 1992.

used to remove fluid simultaneously because oliguria persisted. The membrane oxygenator was replaced 3 days after the initiation of ECMO. The flow rate of ECMO was reduced gradually after 4 days, and the patient was weaned off of ECMO on the sixth day. Hemodialysis was continued for 1 month because of persistent renal failure. Renal function eventually recovered, and the urine output exceeded 1,500 mL/day, with serum urea nitrogen and creatinine concentrations within normal limits. Before ECMO, the glutamic-pyruvic transaminase concentration was 3,678 IU/mL, and it began to decrease soon thereafter. The RAP stabilized at 15 mm Hg 20 days after the operation.

Fig 2. Blood pressure, right atrial pressure, and assisting flow rate after the Fontan procedure. (DBP = diastolic blood pressure; ECMO = extracorporeal membrane oxygenation; POD = postoperative day; RAP = right atrial pressure; REOP = reoperation [the addition of a shunt between the right atrium and left brachiocephalic vein]; SBP = systolic blood pressure.)

Right atrigraphy was performed 3 months after operation and showed that contrast medium from the right atrium drained into the right PA through the graft between the right atrium and left brachiocephalic vein and into the left PA without delay (Fig 3). Respiratory insufficiency due to transient postoperative phrenic nerve palsy necessitated mechanical ventilation for 2 months. The patient subsequently did well and was discharged from the hospital 4 months after the operation. He now lives a normal life with only a restriction on strenuous physical activity.

Comment

The modified Fontan operation has been established as a physiologic correction for tricuspid atresia. However, elevated RAP postoperatively has been a major problem and can lead to renal failure, ascites, and other organ

Fig 3. Right atriography 3 months after the Fontan procedure: large arrows indicate the graft between the right atrium and left brachiocephalic vein, and small arrows indicate the left pulmonary artery.

failure. Kirklin and associates [4] have recommended that a takedown of the Fontan repair should be considered when the immediate postoperative RAP reaches 22 mm Hg. In our patient, the Fontan operation combined with the previous Glenn shunt produced a pressure gradient between the superior vena cava and the IVC, which caused hypertension in the IVC. Although DeLeon and colleagues [5] have noted that the Glenn shunt plays a major role in minimizing postoperative hemodynamic instability, retrospectively, we believed the capacity of the left pulmonary vascular bed was inadequate in this case

and that the Glenn shunt was responsible for the pressure gradient between the superior vena cava and the IVC. The morning after reoperation, the RAP remained markedly elevated (25 mm Hg) despite of the elimination of the pressure gradient. We elected not to take down the Fontan repair but to employ ECMO in the hope that the capacity of the pulmonary vascular bed would increase rapidly. In fact, the patient was weaned from ECMO within 6 days. Extracorporeal membrane oxygenation is one of the most powerful techniques of circulatory support after repair of congenital heart disease [6]. As in this case, it can stabilize the circulatory state with a decrement in the RAP.

Although it is needless to say that anatomic problems, if present, must be resolved in the first place, ECMO, as an alternative to takedown, should be considered when low cardiac output and oliguria secondary to high RAP occur after Fontan repair.

Thoracoscopic Drainage and Resection of Giant Mediastinal Cyst

Keith S. Naunheim, MD, and Charles H. Andrus, MD

Department of Surgery, St. Louis University Medical Center, St. Louis, Missouri

Video thoracoscopy is being used with increasing frequency by thoracic surgeons. Although initially used primarily for simple diagnostic purposes, improved instrumentation and evolving expertise have allowed for the performance of increasingly complex therapeutic procedures. We present a case of a giant subcarinal bronchogenic cyst in an elderly man with multiple med-

ical problems. The cyst nearly occluded the bronchus intermedius and resulted in recurrent respiratory tract infections. Using video thoracoscopy, the cyst was drained and the wall of the cyst was resected successfully with minimal concomitant morbidity.

(Ann Thorac Surg 1993;55:156-8)

A 68-year-old former steel worker came to the St. Louis University Hospital with a complaint of recurrent respiratory tract infections. During the previous 2 years these infections had occurred more frequently and persisted for 2 to 3 weeks despite oral antibiotics. The infections were characterized by intermittent fevers and chills, a productive cough, and right midthoracic posterior chest pain. A chest roentgenogram showed a 10-cm mediastinal mass (Fig 1A). The presence of this mass was confirmed on a computed tomographic scan, which showed a large cystic lesion in the mediastinum that laterally displaced and compressed the bronchus intermedius (Fig 1B). The computed tomographic findings were read as consistent with a bronchogenic cyst. Bronchoscopy confirmed extrinsic compression on the posterior membranous wall of the trachea, which produced near-occlusion at the bronchus intermedius. An attempt at transbronchial drainage via bronchoscopy was made. No fluid could be drawn through a 19-gauge needle advanced through the widened carina into the area of the cystic mass. Attempts at computed tomography-guided percutaneous drainage also proved unsuccessful. The patient was referred to St. Louis University Hospital for consideration of surgical resection of the cyst to prevent recurrent respiratory tract infections.

The patient had a 60-pack-year smoking history, and pulmonary function tests revealed moderately severe chronic obstructive pulmonary disease with a forced vital capacity of 2.22 L (60% of predicted) and a forced expiratory volume in 1 second of 1.42 L (56% of predicted). In addition, the patient's medical history included two anterior myocardial infarctions in 1985 and 1986 requiring percutaneous transluminal coronary angioplasty for postinfarction angina after each. A third infarction occurred in 1990, and since that time the patient has

continued to have intermittent angina episodes. A recent cardiac catheterization revealed occlusion of the left anterior descending and right coronary arteries with severe anterior apical and inferior hypokinesis. The left ventricular ejection fraction was 0.23 with a left ventricular end-diastolic pressure of 40 mm Hg. The cardiac index was $2.01 \text{ L} \cdot \text{min}^{-1} \cdot \text{m}^{-2}$, and marked pulmonary hypertension was found with a pulmonary artery pressure of 70/35 mm Hg and a peripheral vascular resistance of $402 \text{ dynes} \cdot \text{s/cm}^5$.

The patient was thought to have a major operative risk for thoracotomy and cyst excision. A decision was made to proceed with attempted cyst drainage and resection using video thoracoscopy. At the time of operation, a pulmonary artery thermodilution catheter and arterial line were inserted. The patient underwent intubation with a double-lumen endotracheal tube, was placed in the left lateral decubitus position, and was prepared and draped in standard fashion as if for a right thoracotomy. One-centimeter skin incisions were made in the anterior and midaxillary line in the fifth and sixth intercostal spaces, respectively. Another two 1-cm incisions were made medial to the scapula. A Veress needle was placed through the midaxillary line incision and CO₂ was insufflated to a pressure of 10 mm Hg while the right lumen of the endotracheal tube was opened to air, thus collapsing the right lung. After trocar insertion of an instrumentation port (Autosuture Surgiport; U.S. Surgical Corp, Norwalk, CT), the video element was inserted into the thoracic cavity. All trocars except this first one were inserted under direct thoracoscopic visualization. The right lower lobe was found to be adherent to the anterior surface of the cyst, and these adhesions were taken down by a combination of blunt and cautery dissection. The lung was then retracted with a clamp (Autosuture Endobabcock; U.S. Surgical Corp) to expose the anterior surface of the cyst. A Veress needle was then advanced into the cyst and 240 mL of thick, green mucoid material was removed. Cultures for aerobic and anaerobic bacteria, fungus, and acid-fast bacillus were obtained. After the aspiration, the

cyst wall was grasped with a clamp, and using blunt and cautery dissection, the posterior aspect of the cyst was then dissected off the esophagus and vagus nerves. Once the lateral cyst wall had been dissected as far medially as the right main pulmonary artery and superior pulmonary vein, the cyst wall was resected using the cautery. This left a small portion of epithelial-lined cyst wall covering the underside of the right pulmonary artery, the carina, and the posterior left atrial aspect of the pericardium. The wound was liberally irrigated with a 1% bacitracin solution, and hemostasis was obtained with the cautery. Two chest tubes were inserted through the anterior and mid-axillary trocar sites. These tubes were left in the anterior and posterior aspects of the pleural cavity, and the lung was then reexpanded. The operative time excluding anesthesia was 3 hours 45 minutes, and estimated blood loss was 400 mL.

The patient was extubated the following morning. A postoperative chest roentgenogram showed that the mass was gone and a small air fluid level remained in the subcarinal area. The chest tubes were removed on the second postoperative day, and the patient was discharged home on the third postoperative day and resumed his normal activities on the same day. All intraoperative cultures of the cyst wall and fluid yielded no growth.

In the 9 months since discharge, no respiratory tract infections have occurred, and chest roentgenogram reveals no evidence of cyst recurrence.

Comment

Video thoracoscopy is a relatively new technique that presently comprises but a small portion of the practice for most thoracic surgeons. Although video thoracoscopy has been used in the past mainly for exploratory and diagnostic purposes, recently practitioners have broadened the utilization of this technique for bullectomy [1], thoracic sympathectomy [2], empyema drainage [3], lung biopsy [4], and pericardial drainage [5]. The patient presented herein carried a very high operative risk no matter what approach was chosen, as the risk of general anesthesia alone was clinically significant. Although there is certainly a risk of fluid reaccumulation and cyst recurrence after this subtotal resection, this minimally invasive approach seemed most appropriate for this elderly and debilitated gentleman. This thoracoscopic approach was certainly less invasive and morbid than a thoracotomy, which yields major postoperative pain and ventilatory compromise (with a resultant increased risk of pneumonia and respiratory insufficiency). In addition, the time of hospitalization and recuperation was far shorter than would have been the case with a major invasive procedure.

As new techniques evolve and appropriate surgical instrumentation is developed, it is likely that more procedures will prove amenable to this approach. However, as noted in a recent editorial [6], it is important that physicians not allow themselves to be seduced into surgical compromises because of apparent technologic advances. For example, although minimal resections for bronchogenic carcinoma can be accomplished using video thoracoscopy, it will probably prove to be appropriate only for a small number of lung cancer patients [4]. It is important not to allow the desirability of minimally invasive surgery to result in an operation that may compromise the long-term outcome. Before time-tested practices and procedures are abandoned, prospective studies documenting the efficacy of the thoracoscopic approach must first be reported. The organization of a multiinstitutional cooperative study group is already underway and will be a major step toward this goal (J LoCicero III; personal communication).

REVIEW OF RECENT BOOKS

Cardiac and Noncardiac Complications of Open Heart Surgery: Prevention, Diagnosis and Treatment

Edited by Morris N. Kotler, MD, and Anthony Alfieri, DO
Mt. Kisco, NY, Futura, 1992
418 pp, illustrated, \$62.00

Reviewed by Joe W. R. Bolton, MD

This book represents a good medical overview of the preoperative evaluation and postoperative recognition and treatment of the complications of cardiac operations. It is well-referenced and up-to-date, and contains excellent tables, which are aptly discussed in the text. The book admittedly does not contain information concerning the heart transplant patient or the congenital heart patient. It also does not discuss intraoperative complications but limits itself to the medical issues outside the operating suite.

The first chapter presents a superb discussion of the indications for surgical and medical therapy for patients with coronary artery disease. It is based predominantly on a review of the results of the Coronary Artery Surgery Study, the Veterans Administration Cooperative Study, and the European Coronary Surgery Study. Risk factors, survival data, and patency rates are

all discussed in a logical and concise fashion, leading to current recommendations for therapy.

Similarly, the final chapter concerning the prevention of progressive atherosclerosis in coronary artery bypass patients addresses a problem not often discussed in books on the complications of cardiac operations. It reviews the pathophysiology of coronary atherosclerosis in the preoperative and postoperative patient and discusses the current modalities for the prevention and regression of coronary atherosclerosis including dietary changes, drug therapy, and lifestyle changes such as exercise and stress management.

The intervening chapters offer clear, succinct discussions on issues ranging from cardiac complications such as cardiac dysrhythmias and low output syndromes to noncardiac complications such as infections, gastroenterologic, endocrine, hematologic, pulmonary, neurologic, psychiatric, and renal complications.

Overall, the text represents an up-to-date, well-referenced, and well-organized work. It is certainly an easy to read, useful reference for the intensive care unit, postoperative ward, and physician involved in the care of those adult patients undergoing cardiac operations.

Combined Thrombolytic Therapy for Prosthetic Mitral Valve Thrombosis

Charles M. T. Jost, MD, Clyde W. Yancy, Jr, MD, and W. Steves Ring, MD

Division of Cardiology, Department of Internal Medicine, Division of Cardiothoracic Surgery, Department of Surgery; and the Harry S. Moss Heart Center, the University of Texas Southwestern Medical Center at Dallas, Dallas, Texas

Prosthetic valve thrombosis is associated with high mortality. The treatment of choice remains operation. This is a case report of the successful combination therapy of tissue plasminogen activator and urokinase for an isolated thrombosed prosthetic mitral valve in a postpartum patient in whom operation was thought to carry an

unacceptable risk. Combined thrombolytic therapy or therapy with a single agent with a long half-life and a prolonged infusion time is suggested as an emergent treatment option for prosthetic mitral valve thrombosis.

(*Ann Thorac Surg* 1993;55:159-61)

Prosthetic cardiac valve thrombosis, which has an incidence rate of 0.5% to 6%, is associated with a high mortality (60% to 80%) [1]. The mechanism for obstruction represents a spectrum between chronic pannus formation [2] and acute or subacute thrombosis. The location of the valve prosthesis seems to be important in terms of frequency of thrombosis, with the tricuspid valve site carrying the highest percentage (up to 20%) of thrombosis [3], followed by the mitral valve and the aortic valve, respectively. The mortality for an emergency operation depends on different parameters, such as age and left ventricular function, and varies between 35% to 55% for the critically ill patient and 4.7% for very stable patients in a good functional class. For the past two decades there have been numerous sporadic reports on thrombolytic therapy used either as a temporizing measure for semielective operation in lower risk patients or as a curative process. Most case reports of tissue plasminogen activator (TPA) have been for cases of prosthetic tricuspid valve thrombosis [4]. To the best of our knowledge only 1 case has been reported of the use of TPA in association with streptokinase in a patient with tricuspid and mitral valve thrombosis [5]. This is a case report of the probable failure of TPA followed by a successful rescue administration of urokinase for an isolated thrombosed prosthetic mitral valve in a postpartum patient at extremely high risk for operation.

A 16-year-old black girl was admitted to the coronary care unit at Parkland Memorial Hospital for postpartum congestive heart failure. When she was 8 years old, pancarditis had developed secondary to rheumatic heart disease. Mitral insufficiency later developed with symptoms of left ventricular dysfunction over the next 3 years, leading to mitral valve replacement with a Medtronic-Hall valve

(27-mm) when the patient was 11 years old. At that time, cardiac catheterization also showed mild to moderate aortic insufficiency. Three months later she had severe orthopnea and dyspnea with evidence of left and right ventricular dysfunction on physical examination. An echocardiogram revealed four-chamber dilatation, moderately depressed left and right systolic ventricular function, and severe aortic insufficiency without mitral regurgitation. She underwent aortic valve replacement with a St. Jude valve (23-mm) with a good postoperative recovery.

Despite recommendations to the contrary, the patient became pregnant and refused abortion. Subcutaneous heparinization was recommended as the primary method of anticoagulation for the remainder of her pregnancy. At the 33rd week of pregnancy, she was hospitalized after having contractions, increased blood pressure, 2⁺ proteinuria, dyspnea, and evidence of inadequate anticoagulation. The diagnosis of preeclampsia was suggested, and the patient was started on a regimen of intravenous magnesium and intravenous heparin. Physical examination showed no evidence of congestive heart failure, but chest roentgenogram showed cardiomegaly and pulmonary vascular redistribution. Opening and closing clicks of both valves were distinctly heard. Anticoagulation was stopped for the delivery and resumed 6 hours after.

Oliguria developed and the patient was transferred to the coronary care unit for increased tachypnea, acidosis, and pulmonary edema. At that time she had a muffled mitral valve closing click and no opening click. An emergency echocardiogram revealed severe left ventricular systolic dysfunction, pulmonary hypertension, severe tricuspid insufficiency, and moderate aortic insufficiency. A probable mitral valve thrombosis was suggested, and the mitral valve area was calculated by the pressure half-time method as 0.6 cm², decreased from 1.9 cm² 6 months before the admission. A transesophageal echocardiogram showed a mass consistent with a thrombus on the mitral prosthetic valve and very poor left ventricular systolic function.

A surgical consult suggested that the operative mortal-

ity was prohibitive, and thrombolytic therapy was elected. A pulmonary arterial catheter revealed a cardiac output of 1.78 L/min by thermodilution (1.9 L/min by Fick equation), a pulmonary capillary wedge pressure of 30 mm Hg, and a pulmonary systolic pressure of 100 mm Hg. Tissue plasminogen activator was given through the pulmonary artery catheter as a 20-mg bolus, then 50 mg for the first hour and 30 mg for the second hour. After the TPA infusion the patient sustained serious vaginal bleeding requiring vasopressin and cryoprecipitate. Her hemodynamic status improved (cardiac output of 5 L/min) with decreased pulmonary hypertension. Her prosthetic mitral valve opening click remained absent several hours after thrombolytic therapy despite adequate heparinization after controlling the vaginal bleeding. An echocardiogram revealed an ongoing mitral valve thrombus. A few hours later, the patient experienced further hemodynamic compromise requiring intubation. In view of her previous history of rheumatic heart disease, streptokinase was thought to be relatively contraindicated and therefore urokinase was infused at 4500 U/kg over 12 hours. There was progressive improvement in her hemodynamics and the mitral valve opening click was again audible on physical examination at the end of the infusion. An echocardiogram revealed a mitral valve area of 1.2 cm² and the absence of thrombus. Fluoroscopy confirmed reduced opening angle of the mitral prosthetic valve consistent with chronic pannus formation.

A week later while receiving warfarin only (prothrombin time of 19 seconds) she experienced nystagmus and diplopia, which resolved after a few hours. Subsequently she had another transient ischemic attack with right-sided weakness and dysarthria. A high-resolution computed tomographic scan revealed cerebral emboli. However, surgical intervention was still thought to carry an unacceptable risk and the patient was maintained on heparin followed by warfarin with a prothrombin time maintained at 22 to 25 seconds without other embolic evidence. Her predischARGE ejection fraction was 0.50, and the patient remained asymptomatic at 6-month follow-up.

Comment

The treatment of choice for prosthetic valve thrombosis remains operation. However, the very poor left ventricular systolic function of our patient placed her at an unacceptable risk for a third cardiac operation. The postpartum state and related bleeding condition prompted us to choose TPA because this agent has been associated with less systemic fibrinolysis. Low-dose TPA has recently been advocated for tricuspid valve thrombosis with good results, but because TPA was never used as a sole thrombolytic agent for prosthetic mitral valve thrombosis, we chose to administer a full dose of TPA over a 2-hour period. The transient improvement followed by hemodynamic deterioration confirm that a short course of TPA or TPA as the only thrombolytic agent may contribute to but is probably not sufficient for successful prosthetic mitral valve thrombolysis. The consistent improvement after urokinase administration points toward the justification

for a thrombolytic agent with a long half-life or perhaps an extended TPA infusion as suggested for the treatment of tricuspid valve thrombosis [6]. This could have potentially more thrombolytic effect, but this remains unproven for mitral valve thrombosis. Even the long half-life of streptokinase or urokinase infused over 12 hours does not necessarily guarantee success. Indeed, 7 of 26 patients in the series reported by Ledain and associates [7] required a dose of another thrombolytic agent. So it appears that 12 hours is a minimum infusion time for a mitral valve thrombosis and that an extension to 24 to 36 hours [7] should be considered.

Our patient probably had a chronic pannus formation, as shown by the reduced opening angle of the mitral valve after thrombolysis. The hypercoagulable state of the post-delivery period and the termination of heparin administration before delivery have precipitated the formation of acute thrombosis superimposed on a probable chronic pannus. The latter has been shown to be present in up to 46% of cases of any valve obstruction [8]. In this case the pannus may have developed in the long period of inadequate anticoagulation in this noncompliant patient. As pointed out by Deviri and associates [8], not all patients with subacute valve obstruction are symptomatic. The decision to debride the pannus or replace the valve is debatable, and the early surgical mortality rate for prosthesis declotting and excision of the pannus is comparable with that of valve prosthesis replacement [8]. In our case the patient refused operation.

It has been suggested that thrombolytic therapy should not be used for left-sided thrombosis due to high risks of systemic embolization [9]. Indeed, this risk ranges from 15% and 25%, although most of the patients will recover spontaneously or with further thrombolysis because these are typically microemboli and rarely associated with permanent sequelae. A high dose of warfarin to maintain the prothrombin time between 22 and 25 seconds as suggested by our case report might be beneficial in the first few weeks after prosthetic valve thrombolysis.

In summary, TPA as a sole thrombolytic modality may be insufficient for prosthetic mitral valve thrombosis, but combined with streptokinase [5] or with urokinase it may be curative or at least provide hemodynamic stability and improvement in cardiac function for the patients in whom operation is associated with an excessive mortality risk.

We gratefully acknowledge Dr Ron Victor, Dr Benjamin Levine, Dr Paul Grayburn, Dr L. David Hillis, Dr Ivor Benjamin, Dr James T. Willerson, and Dr Susan Pryor for their comments, and John Prior, Richard Cooley, and the staff of the coronary care unit at Parkland Memorial Hospital for technical support.

Free Splenic Artery Used in Aortocoronary Bypass

Dale K. Mueller, MD, Bradford P. Blakeman, MD, and Jack Pickleman, MD

Department of Thoracic and Cardiovascular Surgery, Loyola University Medical Center, Maywood, Illinois

Many alternative bypass conduits for coronary revascularization have been used since the introduction of the saphenous vein. The internal mammary artery has demonstrated superior long-term patency rates compared with vein grafts. Other arterial grafts previously investigated include the right gastroepiploic artery, inferior

epigastric artery, radial artery, and splenic artery. This case reports bypass using a free splenic artery and a pedicled right gastroepiploic artery, each with successful postoperative patency.

(*Ann Thorac Surg* 1993;55:162-3)

Aortocoronary bypass grafts have extremely high patency rates with the use of the internal mammary artery (IMA). Use of the saphenous vein as an arterial conduit also provides for excellent revascularization. Because of the need for additional conduits, particularly in redo revascularization cases, alternative arterial grafts have been investigated including: (1) right gastroepiploic artery (RGEA), (2) inferior epigastric artery, (3) radial artery, and (4) splenic artery. The splenic artery has been used only as a pedicled graft, whereas the IMA and RGEA arteries have been used both as a free graft and as a pedicled graft [1, 2]. The radial artery and inferior epigastric artery for obvious reasons have only been used as a free graft [3-5]. Reported is a case in which the splenic artery as a free graft and an in-situ RGEA were used with successful postoperative patency.

The patient was a 67-year-old woman who came to the emergency room complaining of chest pain, dyspnea, and orthopnea. Medical history revealed the patient had coronary artery bypass grafting four times—the two most recent with cadaver veins. Coronary angiography showed thrombosis of the recent cadaver vein grafts to the left anterior descending and the obtuse marginal arteries. During the angiography the patient complained of rest angina requiring intraaortic balloon pump insertion. Thrombolytic therapy was attempted without success. No infarction had occurred, and the left ventricular ejection fraction remained 0.28.

The patient was taken to the operating room for revascularization of the left anterior descending artery and the obtuse marginal artery. During the previous four operations, all greater saphenous veins, lesser saphenous veins, cephalic veins, inferior epigastric arteries, and both IMAs had been used or determined to be unsuitable for use. Cadaver veins had been used for the two most recent bypass procedures. Also, the patient had no palpable radial pulses in either arm, thereby eliminating this vessel as a potential conduit. Multiple angioplasties had also

been attempted with dismal results. Aortocoronary bypass grafting was performed using the RGEA anastomosed to the obtuse marginal artery and the free splenic artery to the left anterior descending artery. Excellent Doppler pulses were present for both grafts.

The patient's postoperative course was complicated by pneumonia, bacteremia, and a urinary tract infection. The patient at 7 months is asymptomatic and has demonstrated no clinical signs of ischemia. An adenosine thallium stress test was obtained postoperatively and demonstrated no areas of reversible ischemia. Because of severe peripheral vascular disease, it was decided not to repeat coronary angiography. In fact, since the operation the patient has required an axillo bifemoral artery bypass graft.

Comment

Since the origin of coronary revascularization, surgeons and cardiologists have searched for the optimal vascular conduit. The saphenous vein graft has been the primary graft used. However, more reliable grafts have been desired because patency rates for veins are 70% to 80% in men and approximately 10% to 15% lower in women [6].

Thus far the optimal bypass graft has been the IMA [6]. Although technically more difficult, the IMA provides superior patency compared with any other graft thus far investigated. The Cleveland Clinic has recommended that the IMA be the first choice for coronary revascularization. The RGEA has also been investigated, with two studies demonstrating excellent early patency of RGEA when used as a pedicled or free graft [7, 8]. Experience with the inferior epigastric artery is also limited, and current literature concerning the free radial artery demonstrates approximately 33% patency [3, 4].

Edwards and associates [1] in 1973 employed the splenic artery as an in-situ graft passing through the membranous portion of the diaphragm and anastomosed to the distal right coronary artery. The splenic artery was mobilized behind the pancreas at the junction of the body and tail with obligatory splenectomy. Two postoperative splenic artery angiograms demonstrated widely patent anastomosis. Potential disadvantages of using the splenic artery were noted to be its tortuous course and larger

Accepted for publication April 9, 1992.

diameter as compared with the right coronary artery. Edwards and associates [1] did not find these to be major problems.

A free splenic artery bypass graft to the left anterior descending and a pedicled RGEA bypass graft to the obtuse marginal artery were performed in our patient. The midsternotomy incision was extended to the umbilicus. After the right gastroepiploic artery pedicle was freed, the lesser sac was entered. The splenic artery was identified along the upper border of the pancreas. Beginning at the middle of the artery, the dissection proceeded medially to its origin from the celiac axis. Multiple small branches pass from the splenic artery to the pancreas, and each was carefully ligated. Also, great care was taken to avoid any injury to the pancreas. Next the dissection proceeded laterally. Once the tail of the pancreas was reached the spleen was freed from its lateral attachments. The short gastrics were divided, and the artery was divided after branching occurred. An obligatory splenectomy was performed. The original intent was to use the splenic artery as an in-situ bypass graft for the obtuse marginal artery; however, the length was inadequate. It was therefore divided at the celiac axis and used as a free graft to the anterior descending vessel. Four technical aspects of using this vessel merit mention. First, the majority of the tortuosity can be straightened by dividing the surrounding tissue. Second, the intima was extremely friable near the splenic hilum, necessitating meticulous suturing. Third, the splenic artery possessed diffuse calcification, which made the anastomosis more difficult, but possible. Finally it must be emphasized that meticulous dissection should be performed at the upper surface of the

pancreas to avoid any injury of this organ and potential pancreatitis.

In conclusion, this patient represents an increasing number of complex redo revascularizations that all surgeons will face. The splenic artery is offered as a potential conduit in an extremely desperate situation. Short length of the splenic artery will limit its use to the posterior descending vessel as an in-situ graft and to the anterior descending vessel or diagonal branch as a free graft. The IMA and saphenous vein graft remain the conduits of choice for most patients.

Treatment of Incessant Reciprocating Atrioventricular Tachycardia by a Closed Heart Surgical Technique

Yves A. G. Louagie, MD, Luc De Roy, MD, and Jean-Claude Schoevaerds, MD

Division of Cardiovascular and Thoracic Surgery and Division of Cardiology, Academic Hospital of Mont-Godinne (Catholic University of Louvain), Yvoir, Belgium

The case of a 40-year-old woman having disabling symptoms of incessant atrioventricular reciprocating tachycardia is reported. She underwent surgical therapy by a closed heart technique. Operative technique and the advantages of the epicardial approach in the present case are detailed.

(*Ann Thorac Surg* 1993;55:164-6)

The permanent form of junctional reciprocating tachycardia is considered to be a variant of preexcitation syndromes. This incessant tachycardia with a normal QRS was first described by Coumel and associates in 1967 [1]. The arrhythmia is a reciprocating tachycardia with the antegrade limb in the atrioventricular node and a retrograde limb with decremental functional properties in the septal ventriculoatrial area. It is associated with severe cardiac dysfunction and is poorly responsive to pharmacologic treatment. The current therapeutic modalities include destruction of the retrograde limb by radiofrequency catheter ablation [2] and surgical section by an endocardial approach [3, 4] or by a closed heart technique [4, 5].

Because, to our knowledge, surgical ablation of the accessory pathway using an epicardial approach without cardiopulmonary bypass has been reported in only 8 patients [4, 5], we describe a further patient operated on successfully with the latter technique.

A 40-year-old woman was referred with a 20-year history of rapid heart rate. She complained of palpitations, tiredness, and limited physical activity. Conventional medical therapy including digoxin, β -blocking agents, and amiodarone was unsuccessful in controlling symptoms. The standard electrocardiogram showed the classic features of permanent junctional reciprocating tachycardia, namely, a 1:1 atrioventricular relationship with a marked negative retrograde P wave in leads II, III, and aVF. The P wave occurred closer to the succeeding QRS complex than the preceding one. Holter monitoring demonstrated incessant tachycardia with rates varying between 148 and 90 beats/

min (average, 108 beats/min) and only brief interludes of sinus rhythm. There was typically a pause followed by one sinus cycle before resumption of tachycardia. Electrophysiologic study demonstrated an orthodromic atrioventricular reentry using a concealed accessory pathway with decremental conduction properties. The site of earliest retrograde atrial activation during reciprocating tachycardia was at the coronary sinus orifice. Isotopic left ventricular ejection fraction was 0.30 at rest and increased to 0.37 with a workload of 90 W.

At operation, the heart was exposed through a median sternotomy. Intraoperative cardiac mapping was performed using a 24-electrode epicardial band array and a computer-assisted mapping system (Bard Cardiac Mapping System; Bard, Billerica, MA). The pathway was localized to the posteroseptal region (Fig 1). The operation was performed on the normothermic beating heart without the use of cardiopulmonary bypass, following the technique described by Guiraudon and associates [6]. The right ventricular inferior wall was retracted upward. The epicardium of the right inferior fat pad was incised along its ventricular limits, and the incision was extended medially to the coronary sinus anteriorly. The right coronary artery and its branches were exposed (Fig 2). Further mobilization of the right atrioventricular fat pad gave exposure to the posterior superior process of the left ventricle. Permanent cardiac rhythm monitoring was provided during the procedure, and tachycardia disappeared permanently during dissection of the origin of the posterior descending artery. Concomitantly, we observed an increase in systemic pressure and a decrease in central venous pressure (Fig 3). A cryoprobe 5 mm in diameter (CCS-200; Frigitrionics, Shelton, CT), cooled to -60°C for 2 minutes for each application, was used to complete the ablative procedure. Control mapping showed the absence of premature activation of the posteroseptal area.

The patient was extubated immediately after the procedure and had an uneventful recovery. Pairs of temporary pacing wires implanted over each cardiac chamber were used for the postoperative stimulation study, which demonstrated absence of retrograde conduction over the accessory pathway. Six months after operation, this patient is asymptomatic and fully active. Left ventricular isotopic ejection fraction determined at rest was 0.52.

Accepted for publication April 10, 1992.

Fig 1. Atrial activation map during spontaneous incessant tachycardia. The earliest atrial activation appears in the region near the coronary sinus os and is represented by yellow. The numbers represent the ventriculoatrial conduction times, with the shortest value of 355 ms at the coronary sinus os.

Comment

Division of accessory pathways with a technique that avoids aortic cross-clamping and cold cardioplegic arrest may improve surgical results. Comparison of the endocardial versus epicardial approach in the surgical treatment of the Wolff-Parkinson-White syndrome suggested that the epicardial approach could be advantageous for interrupting accessory pathways of the posterior septal region [7].

In particular, the endocardial approach to the posteroseptal area may induce inadvertent atrioventricular block

Fig 2. Operative view of the dissection of the posteroseptal pathway. The right ventricular inferior wall is retracted upward with a pledget-supported suture. The right coronary artery (RCA) and the posterior descending artery (PDA) are isolated on vessel loops.

Fig 3. (A) Tachycardia and negative retrograde P wave disappeared permanently during dissection of the origin of the posterior descending artery. (B) A concomitant increase in systemic pressure (BP) and decrease in central venous pressure (CVP) were observed. (ECG = electrocardiogram; R = rhythm; TACHY = tachycardia.)

[8]. The closed heart technique performed on a normothermic beating heart prevents permanent atrioventricular block by permitting continuous control of atrioventricular conduction during dissection and cryoablation. In the present case, by monitoring the cessation of the tachycar-

dia, we were able to locate exactly the accessory pathway and concentrate our dissection and cryoablation on that area.

With the increasing availability of radiofrequency catheter ablation techniques, operation for accessory pathways will be realized more selectively. We believe that the posterior septal epicardial approach is well adapted to the difficult cases of failed catheter ablation.

FIRST LINE THERAPY

FOR CHRONIC PLEURAL EFFUSION

The **Denver Pleural Effusion Shunt** can be a first line therapy in the management of chronic effusions. The patients' quality of life may be enhanced by:

- ▶ **Fewer procedures**
- ▶ **Reduced hospital stays**
- ▶ **Retained nutrients**
- ▶ **Reduced infection risk**

With the Denver Pleural Effusion Shunt, patients gain the convenience, independence and comfort of managing their chronic pleural effusions.

An open and shut case

You can see the difference with the naked eye. The Hancock M.O. Bioprosthesis eliminates the flow-impeding septal muscle shelf of the right coronary cusp and replaces it with a noncoronary cusp from a second, larger valve. With three fully flexible leaflets, the Hancock M.O. valve opens more completely and symmetrically during systole compared

with other porcine bioprostheses. Thus, it offers minimal obstruction to blood flow and superior hemodynamics.

This composite design, proven in over 12 years of clinical use, provides excellent hemodynamics in the aortic position. A recent study published in *Circulation* demonstrated that smaller (size 19 and 21mm) Hancock M.O. Bioprostheses

Hancock M.O.
Bioprosthesis

for the modified orifice.

have lower gradients and larger valve areas than comparably sized porcine valves retaining the muscle shelf.¹

Excellent flow characteristics combined with long-term clinical experience make the Hancock M.O. Bioprosthesis the tissue valve of choice for the small aortic root.

Management of a Mediastinal Cyst Causing Hyperparathyroidism and Tracheal Obstruction

Levent Guvendik, FRCS, Lionel K. M. Oo, MB, BS, Somnath Roy, MRCP, Leslie A. Donaldson, FRCS, and David D. Kennedy, FRCPath

Humberside Cardio-thoracic Center, Castle Hill Hospital, Cottingham and Grimsby District General Hospital, Grimsby, United Kingdom

A 78-year-old man with a history of parathyroidectomy presented with hyperparathyroidism and tracheal obstruction. After excision of the mediastinal parathyroid cyst, his symptoms were completely relieved. The diagnosis, investigations, and management are discussed.

(*Ann Thorac Surg* 1993;55:167-8)

Mediastinal parathyroid cysts are rare; only 17 cases have been reported in the literature to date. Only 3 of those had associated hyperparathyroidism [1-4]. Multiple parathyroid adenomas are also extremely rare [5, 6]. This report presents a case of hyperparathyroidism with two cervical parathyroid adenomas and a hyperfunctioning mediastinal parathyroid cyst causing tracheal obstruction and mental depression.

A 78-year-old man was referred to our unit in January 1991 with dyspnea and stridor. Five years before this admission, he had a variety of psychiatric problems, ranging from depression to agitation, and also had recurrent urinary tract infection. He was initially treated with antidepressants and antibiotics.

Ten months later, he was readmitted with a fracture of his pelvis after a fall. A chest radiograph this time showed a superior mediastinal mass (Fig 1), and a radiograph of the abdomen revealed a right renal calculus. He was also found to have a raised serum calcium level of 3.27 mmol/L (normal, 2.2 to 2.6 mmol/L) and a raised parathormone level of 13.41 ng/mL (normal, 0.4 to 1.3 ng/mL). A thallium/technetium 99m scan of the neck and the upper mediastinum failed to show hyperfunctioning parathyroid tissue. He declined to have an operation and was treated with calcitonin and antidepressants.

One year later, he agreed to have surgical exploration of his neck. At the operation, left superior and inferior parathyroid adenomas were removed and a normal right inferior parathyroid gland was preserved. The right superior parathyroid gland could not be found. Biopsies of the mediastinal cyst did not show any evidence of parathyroid tissue. Postoperatively, the serum calcium and parathormone levels were lower (calcium, 3.16 mmol/L;

phosphate, 0.6 mmol/L; parathormone, 4.76 ng/mL) but still remained above the normal range. The patient refused to have further operation.

Two years later, dyspnea and upper respiratory tract stridor led to his current admission to our unit. A computed tomographic scan showed the previous cystic lesion, which had increased in size and was now causing severe tracheal compression (Fig 2). A repeat thallium/technetium scan did not show any enhanced uptake in the mediastinum. At operation, through a right dorsolateral thoracotomy incision, a cyst 8 cm in diameter was located in the posterosuperior mediastinum with a pedicle arising from the right side of the neck. The cyst was excised in toto. The right recurrent nerve could not be identified because of dense adhesions. Microscopically, the mass consisted of dense fibrous and fibrofatty tissue but was devoid of any epithelial lining, with occasional lymphoid foci and several islands of parathyroid tissue. There were clumps of red cells and old blood clots on the inner lining of the cyst indicating previous hemorrhage into the cyst.

After the operation, the serum calcium and parathormone levels returned to normal (calcium, 2.3 mmol/L; parathormone, 1 ng/L). He had mild recurrent nerve palsy, which was treated by Teflon injection with a good result. His mental depression was very much improved.

Comment

Mediastinal parathyroid cysts infrequently occur and rarely cause tracheal obstruction. It is very unusual for these cysts to cause hyperparathyroidism, particularly in association with other adenomas. Multiple parathyroid adenomas are very rare indeed. Wang [5], in his review of 500 cases of hyperparathyroidism, did not find a single patient with multiple adenomas. It is generally accepted that hyperfunctioning adenoma suppresses the other glands, thereby preventing the development of other parathyroid adenomas in the same patient. This certainly was not the case in our patient; not only did he have two cervical adenomas but he also had a mediastinal cyst containing hyperfunctioning parathyroid tissue that continued to secrete enough parathyroid hormone to maintain symptoms of hyperparathyroidism even after successful excision of the cervical adenomas.

Preoperative localization of these cysts is very important. In our patient, there was a strong suspicion of the mediastinal cyst being parathyroid in origin, but the

Accepted for publication April 13, 1992.

Fig 1. Chest radiograph showing a large, round lesion in the superior mediastinum pushing the trachea to the left.

thallium/technetium scan and the biopsy of the cyst were negative. The reported sensitivity of thallium/technetium scan ranges from 92% to 76% [6]. Biopsy of the cyst was not helpful in establishing the diagnosis because islands of parathyroid cells were not homogeneously situated in the wall. Therefore an exploratory operation should be

Fig 2. Computed tomographic scan demonstrating a large cystic lesion causing severe tracheal compression at the level of the superior mediastinum.

performed on clinical grounds if investigations fail to show functioning parathyroid tissue.

The inferior parathyroid glands develop from the third pharyngeal pouch with the thymus. In the ectopic position, they are usually located in the superior mediastinum, whereas the superior glands arise from the fourth pharyngeal pouch and are situated between the superior edge of the larynx and the lower pole of the thyroid gland [7]. In our patient, the right superior parathyroid could not be located and the cyst was in the right posterior mediastinum with the pedicle arising from the right side of the neck. These findings would suggest that this mediastinal parathyroid cyst could have been the ectopic right superior parathyroid gland, which had originated in the neck and had descended into the posterior mediastinum. Enlargement of the cyst leading to tracheal obstruction could have been caused by hemorrhage into the cyst as documented by histological findings.

Although depression is a known complication of hyperparathyroidism, this case is unusual in that depression was associated with a hyperfunctioning mediastinal parathyroid cyst.

It is important that cystic lesions of the mediastinum should be removed for diagnosis, particularly in a patient who has an endocrine abnormality.

We would like to express our gratitude to Dr J. B. Kershaw, Dr H. P. Bury, and Dr P. Martin for their invaluable help with histopathological and biochemical diagnostic work.

Multiple Tumor Emboli After Pneumonectomy

David D. Spencer, DO, Jorge L. de la Garza, MD, and William A. Walker, MD

Division of Cardiothoracic Surgery, Department of Surgery, and Department of Clinical Investigation, Naval Hospital, San Diego, California

Systemic arterial tumor embolization is a rare complication after pulmonary resection. It may occur with primary or metastatic pulmonary malignancies, and is more frequently associated with pneumonectomy than with lesser pulmonary resections. Despite the rarity of this

complication, tumor emboli should be considered in the etiology of extremity, cerebral, or multiorgan ischemia occurring during the perioperative period in patients undergoing pulmonary resections for malignancy.

(Ann Thorac Surg 1993;55:169-71)

Massive systemic tumor emboli complicating pulmonary resection for bronchogenic carcinoma are rare. Similarly, tumor embolization to the cerebral circulation is an uncommon event after lung resection and often not considered as the cause of stroke in the cancer patient [1, 2]. We present our experience with a patient who underwent an extended pneumonectomy for a large, centrally located, bronchogenic tumor.

A 55-year-old man presented with hemoptysis and with right chest and back pain. Physical examination was remarkable only for decreased breath sounds in the lower right hemithorax. Chest roentgenogram showed a centrally located, 12-cm mass in the right lower lobe (Fig 1). A computed tomographic scan of the chest also demonstrated several 1.0-cm to 1.5-cm paratracheal lymph nodes. At bronchoscopy we noted complete obstruction of the superior segment and the posterior-basilar segment of the right lower lobe. Biopsy specimens were diagnostic for a poorly differentiated carcinoma. Preoperative evaluation including laboratory studies, cardiac evaluation, and pulmonary function testing showed no contraindication to major pulmonary resection.

Mediastinoscopy and multiple lymph node biopsies were negative. At thoracotomy, no chest wall or mediastinal involvement was present. Manipulation of the lower lobe was difficult because of the size of the tumor. The pleura overlying the inferior pulmonary vein was thickened, but no tumor was appreciated within the vein. An extended pneumonectomy was performed including a portion of the left atrial wall with the inferior pulmonary vein. Margins were clear by frozen section.

On awakening, the patient complained of pain and partial paralysis in both lower extremities, which were cool and pulseless to examination. Bilateral femoral artery explorations were performed and a large aortic saddle embolus was removed, restoring forward flow to both legs. Frozen section of the embolus demonstrated tumor cells, which were confirmed on permanent sections (Fig 2). Approximately 6 hours later the patient had expressive aphasia and right hemiplegia. A head computed tomographic scan showed an ischemic left frontoparietal infarction consistent with an embolic event. A transesophageal echocardiogram was performed; no tumor or clot was seen within the left atrium.

The patient's neurological status slowly improved. His only subjective complaint was intermittent left leg pain with a normal vascular examination. A repeat computed tomographic scan of the head showed a resolving ischemic infarction. On the 12th postoperative day, he again complained of bilateral lower extremity pain and weakness. His examination was consistent with bilateral ischemia. A repeat exploration of both femoral arteries was promptly performed, and a second saddle embolus was removed from the aorta. Frozen and permanent sections of the embolus again demonstrated tumor cells.

The remainder of his hospitalization was uneventful. His neurological status slowly improved until his transfer to a rehabilitation unit. He thereupon completed an intensive neurological rehabilitation program without further improvement in his right hemiplegia or expressive aphasia. Since his discharge from the hospital, the patient has been unavailable to follow-up examination despite extensive but unsuccessful efforts to locate him. Therefore, his ultimate clinical outcome is not known.

All embolectomy specimens were confirmed pathologically as tumors of the same cell type as the primary pulmonary tumor, a poorly differentiated adenocarcinoma.

Comment

Microscopic evidence of angioinvasion in bronchogenic carcinoma is almost uniformly present if one examines for

Accepted for publication April 13, 1992.

Fig 1. Posteroanterior preoperative chest roentgenogram showing centrally located 12-cm mass in the right lower lobe.

involvement in the tributaries of the pulmonary vein. However, the incidence of macroscopic pulmonary vein invasion by tumor is not well documented but may be up to 34% [3]. The importance of microscopic invasion in regard to long-term prognosis is questionable. The consequence of dislodging macroscopic tumor from the pulmo-

nary vein is often fatal [4]. Fortunately, surgical experience indicates that tumor extending into the proximal pulmonary veins or left atrium is rare and more likely to occur in bulky, centrally located tumors.

This patient had tumor extending into the proximal portion of the inferior pulmonary vein, which was not appreciated at exploration. The surgical manipulation in performing the extended pneumonectomy dislodged a portion of the tumor, resulting in the systemic emboli. The bulk of the tumor embolus lodged in the distal aorta and the aortic bifurcation, causing the lower extremity ischemia. The cerebral infarction presumably was the result of left middle cerebral artery embolization by a neoplastic mass, which was retained in the left atrium and dislodged in the immediate perioperative period. After two embolic events, a transesophageal echocardiogram was performed but showed no residual intraatrial mass. It is postulated that the second aortic saddle embolus, occurring 12 days after the first embolus and the negative transesophageal echocardiogram, resulted from a tumor embolus that initially lodged in the aorta proximal to the bifurcation.

To minimize the risk of tumor dislodgment during surgical manipulation, some authors recommend early ligation of the pulmonary veins. In patients with large central tumors who may be at increased risk for tumor dislodgment, early pulmonary vein ligation may be warranted. However, this procedure may be difficult or impossible to perform because of the size of the tumor.

In selected patients in whom an extended pneumonectomy is anticipated, consideration should be given to obtaining a preoperative transthoracic or transesophageal echocardiogram to evaluate for the presence of tumor within the pulmonary veins or left atrium; this examination can be performed before the thoracotomy. If tumor is

Fig 2. Tumor embolus. (Both stained with hematoxylin and eosin: left, $\times 100$; right, $\times 250$; both before 38% reduction.)

identified within the veins or atrium, modification of the surgical technique or the extent of resection will allow for a complete resection of tumor and possibly avoid the complication of systemic tumor emboli. Finally, tumor embolization, although uncommon, should be given consideration in the etiology of cerebral, extremity, or multiple organ ischemia that occurs in the perioperative period in patients undergoing pulmonary resection for malignancy.

Preoperative Management of Neonatal Tetralogy of Fallot With Absent Pulmonary Valve Syndrome

Markus K. Heinemann, MD, and Frank L. Hanley, MD

Department of Cardiac Surgery, The Children's Hospital, Harvard Medical School, Boston, Massachusetts

In tetralogy of Fallot with absent pulmonary valve syndrome, aneurysmal enlargement of the central pulmonary arteries can be associated with severe bronchial stenosis and respiratory distress in the neonatal period. The ventilatory status of these patients must be stabilized

before diagnostic and therapeutic interventions can be performed. This report describes the experience with prone positioning and emergency sternotomy in the preoperative care of a neonate.

(Ann Thorac Surg 1993;55:172-4)

Absent pulmonary valve syndrome accounts for 3% of all cases of tetralogy of Fallot. It consists of agenesis of the pulmonary valve with pulmonary insufficiency and annular pulmonary stenosis. The central pulmonary arteries are aneurysmally enlarged and may compress the tracheobronchial tree. The degree of this compression determines the clinical presentation. Severe obstruction can render the patient critically ill in the neonatal period. Respiratory failure may be predominant and necessitate emergency relief of the tracheobronchial compression.

A 3.6-kg male neonate was referred on the first day of life for evaluation and treatment of profound cyanosis and respiratory acidosis. At birth, endotracheal intubation and mechanical ventilation were necessary. However, respiratory function remained severely compromised during transfer to our institution. Echocardiography showed tetralogy of Fallot with absent pulmonary valve syndrome and massive central pulmonary artery aneurysms (diameter, 16 mm). Adequate ventilation could only be achieved with the infant in the prone position. In the supine position there was an instant increase in carbon dioxide tension and a decrease in oxygen tension (Table 1). He therefore underwent repair of his cardiac malformation.

During preparation for the surgical procedure the patient was repositioned on the operating table from the prone to the supine position for sternotomy. An immediate increase in the carbon dioxide level was noted, although the inspired oxygen fraction had been increased from 0.3 to 1.0. Emergency sternotomy was performed. Upon this, there was obvious immediate clinical improvement in his mechanical gas exchange, documented by consecutive blood gas analyses, before cardiopulmonary bypass was instituted (see Table 1).

Hypothermic circulatory arrest was established, and the

lesion was repaired. This included ventricular septal defect closure and aneurysmorrhaphy of the massively dilated main and branch pulmonary arteries, reducing them to normal size. In addition, a valved aortic homograft conduit (diameter, 9 mm) was implanted to reconstruct the right ventricular outflow tract, keeping its length short to lift the branch pulmonary arteries off the tracheobronchial structures.

Postoperatively there were stable hemodynamics and no carbon dioxide retention in the supine position as long as full ventilation was provided. However, attempts to wean the patient from the ventilator were unsuccessful for 2 weeks because of hypercapnia. Cardiac catheterization revealed relatively normal intracardiac hemodynamics with a right ventricular pressure about half systemic and no major shunts. There was residual distortion and dilation of the intraparenchymal lobar pulmonary arteries (Fig 1). Concomitant bronchography disclosed diffuse areas of narrowing in the secondary branches of the tracheobronchial tree, especially in the left lung (Fig 2). The patient was eventually extubated on the 31st postoperative day.

Since then the boy has suffered repeated upper respiratory tract infections, sometimes necessitating hospital treatment but never mechanical ventilation. There has been slow but constant improvement of his respiratory status, and he is now 2 years of age. No further operation has been necessary.

Comment

Tetralogy of Fallot with absent pulmonary valve syndrome may be seen in infancy with severe respiratory distress, caused by central airway compression by the enlarged pulmonary arteries. Early surgical correction including plasty of the pulmonary arteries has been advocated [1-5]. Mortality is still considerable owing to the poor clinical condition of the patients. An already decreased air exchange can be made even worse by additional intrapulmonary bronchial stenoses caused by abnormally branching peripheral pulmonary arteries [6].

Table 1. Respiratory Status Data Varying With Positioning

Variable	Admission Day, ICU		Day of Operation			
	Supine	Prone	Before Sternotomy		After Sternotomy	
			Prone, OR	Supine, OR	10 Min	20 min
Pco ₂ (mm Hg)	60	34	40	69	57	35
Po ₂ (mm Hg)	22	56	67	68	149	358
pH	7.36	7.53	7.50	7.27	7.35	7.54
FiO ₂	0.3	0.3	0.3	1.0	1.0	1.0
Ventil	SIMV	SIMV	SIMV	CMV	CMV	CMV

CMV = continuous mandatory ventilation; FiO₂ = fraction of inspired oxygen; ICU = intensive care unit; OR = operating room; Pco₂ = partial pressure of carbon dioxide in arterial blood; Po₂ = partial pressure of oxygen in arterial blood; pH = acid-base status; SIMV = synchronized intermittent mandatory ventilation; ventil = mode of ventilation.

The airway obstruction should be relieved as completely as possible preoperatively, but intractable respiratory symptoms have been the main indication for emergency operation [1, 4, 5].

The preoperative clinical improvement of infants with symptomatic absent pulmonary valve syndrome in the prone position has been noted [7, 8]. This phenomenon is explained by the position of the enlarged pulmonary arteries, which fall posteriorly when the patient lies supine, thereby compressing the bronchi behind them.

A supine position is necessary for performing a median sternotomy. In the most severely compromised patients even short periods in this position may be tolerated poorly. In our case median sternotomy dramatically reversed this process (see Table 1). An awareness of this may prevent prebypass respiratory arrest in the operating room and also avoid "crashing" on bypass. One may speculate that in such patients, who also may require more prolonged resuscitation in the intensive care unit or

further diagnostic studies before operation is undertaken, an elective median sternotomy could be quite helpful in the overall management. This would allow the supine position to be tolerated for performance of various procedures, ranging from vascular access to cardiac catheterization. The wound can be sealed with a prosthetic patch.

Primary complete repair including ventricular septal defect closure, decompression of the airways by reduction plasty of the enlarged segments of the central pulmonary arteries, and valved homograft reconstruction of the main pulmonary artery is advocated by us for the treatment of symptomatic absent pulmonary valve syndrome in infancy. Additional intrapulmonary bronchovascular anomalies may contribute to severe respiratory problems after correction, as illustrated by our patient. It therefore seems appropriate to normalize the cardiovascular status as much as possible by complete repair including the placement of a pulmonary valve. Our philosophy is that any residual cardiac handicap, even one normally well toler-

Fig 1. Cardiac catheterization on the 14th postoperative day: pulmonary arteriogram in anteroposterior position after reconstruction of the right ventricular outflow tract and the main pulmonary artery with a valved aortic homograft conduit, and after extensive reduction plasty of left and right pulmonary artery to diameters of about 5 mm. Distorted and still dilated proximal lobar pulmonary arteries can be seen. The regurgitation into the right ventricle is caused by the position of the catheter.

Fig 2. Bronchogram in anteroposterior position performed during the cardiac catheterization on postoperative day 14. Diffuse areas of narrowing can be seen in the secondary branches of the tracheobronchial tree: right middle and lower lobe, lingula, and especially left upper and lower lobe.

ated in standard tetralogy of Fallot, can have a devastating effect in the presence of inevitable long-term pulmonary disease.

Retrograde Cardioplegia Cannulation During Cardiopulmonary Bypass

Alexander S. Geha, MD, and Jai H. Lee, MD

Division of Cardiothoracic Surgery, Case Western Reserve University School of Medicine and University Hospitals of Cleveland, Cleveland, Ohio

A simplified method of transatrial cannulation of the coronary sinus during cardiopulmonary bypass, with the heart completely decompressed, is described. The technique is easy to adopt and inherently safe because the catheter is guided toward the great cardiac vein visually, rather than by manual palpation.

(*Ann Thorac Surg* 1993;55:175-6)

Transatrial cannulation of the coronary sinus for the purpose of delivery of cardioplegia through the retrograde route has been efficacious in a variety of cardiac operations. The details of the technique as described by Gundry and associates [1] and Drinkwater and colleagues [2] involve placement of the retrograde cannula by manual palpation of the right atrioventricular groove to guide the catheter into the coronary sinus before establishment of cardiopulmonary bypass. Although facile in experienced hands, prolonged manipulation, which may occur, can result in hemodynamic instability and arrhythmias. Cannulation by palpation is also a partially blind technique, and misplacement of the catheter into a tributary of the coronary vein and even coronary sinus rupture are recognized complications that can occur.

We describe a technique that we have developed over the past year, which allows for rapid placement of the retrograde catheter after cardiopulmonary bypass is initiated. This technique is also different from that described in the recent communication by Arom and Emery [3] in that the catheter is positioned not by palpation, but by visually guiding it into the coronary sinus and the greater cardiac vein.

Technique

Cardiopulmonary bypass is initiated in standard fashion with aortic cannulation and a single venous cannula. The heart is completely decompressed. With the heart beating, the retrograde catheter is introduced into the right atrium through a small stab wound within a pursestring suture, which is then held up by the assistant to create an airtight seal. It is preferable to place the pursestring suture low in the right atrium.

From the surgeon's side, the heart is retracted cephalad with the left hand, visualizing the atrioventricular groove (Fig 1). With the right hand, the retrograde catheter with its tip gently curved (either by shaping the flexible stylet, or preferably by using a catheter with a preformed stylet) is guided and seen to engage the coronary sinus. At this juncture, it is a simple matter to then guide the tip of the catheter beyond the posterior interventricular vein by advancing the catheter itself without the stylet. Because the course of the great cardiac vein is visualized at all times, precise and safe placement is assured in every instance. We usually cannulate the coronary sinus shortly after cardiopulmonary bypass has been established, while the heart is still beating; however, this maneuver can be performed in the same way with the heart fibrillating.

The details are the same if one wishes to place the catheter from the assistant's side. The heart is retracted cephalad with the left hand, and the catheter is guided into the coronary sinus with the right hand. The visualization of the course of the great cardiac vein is equally good from this side, and therefore, the technique is equally facile and safe.

Fig 1. The heart is retracted cephalad from the surgeon's side with the left hand after cardiopulmonary bypass is initiated. The tip of the two-stage venous cannula is seen in the inferior vena cava. The great cardiac vein is visualized as the catheter engages the coronary sinus. The stylet is then withdrawn, and the tip of the catheter is guided distally.

Comment

Early in our experience with retrograde cardioplegia, we initially adopted the technique described by Gundry and associates [1]. However, it became clear that there was a learning curve associated with this technique that inhibited more widespread acceptance. Also, the disadvantages of provoking hemodynamic instability while attempting to place the catheter before cardiopulmonary bypass and the small but finite risk of perforation of the coronary sinus with the technique of manual palpation became apparent.

Over the past year, the technique as described has been used as the sole method for transatrial cannulation of the coronary sinus in the 204 patients in whom this approach was indicated, including coronary bypass and mitral and aortic valve operations. We have used preferentially the Retroplegia cannula (Research Medical, Inc, Salt Lake City, UT) because we find the preformed stylet of this catheter to lend itself best to this technique. We have noted successful cannulation in all but 4 patients, with the average time being less than 10 seconds. In 4 patients, we

were unable to direct the catheter beyond the posterior interventricular vein although the catheter was seen to engage the coronary sinus. Presumably this was due to the presence of a flap or valve in the coronary sinus orifice. In these patients we administered cardioplegia antegradely and through the vein grafts. The incidence of iatrogenic injury to the coronary sinus has been nil. We present this technique as an added approach to the armamentarium of the surgeon in achieving safe myocardial protection.

Simplified Method for Delivering Normothermic Blood Cardioplegia

Philippe Menasché, MD, PhD, Bernard Touchot, MD, Frédéric Pradier, DPharm, Gérard Bloch, MD, and Armand Piwnica, MD

Department of Cardiovascular Surgery, Hôpital Lariboisière, and Pharmacie Centrale de l'Assistance Publique-Hôpitaux de Paris, Paris, France

We describe a simple technique for optimizing oxygen delivery during normothermic continuous blood cardioplegia. It involves the use of a minimal volume of cardioplegic agents, the infusion rate of which is adjusted so as to keep the heart arrested. The resulting enhancement of oxygen supply is marshalled from the maintenance of hematocrit values in the range of 0.25.

(*Ann Thorac Surg* 1993;55:177-8)

Normothermic continuous blood cardioplegia is a recently described technique [1] that has yielded very encouraging results, in particular in patients at high operative risk because of impaired left ventricular function [2] or long cross-clamping time [3]. Until now, normothermic continuous blood cardioplegia has been used in the same manner as cold blood cardioplegia, that is, blood is diluted with crystalloid cardioplegic solution in a 4:1 ratio. In practice, the technique requires two cardioplegic solutions, one (high K^+) for inducing and the other (low K^+) for maintaining arrest, with an eventual switch back-and-forth between the two perfusates if there is recurrence of cardiac activity during the cross-clamping period. The whole cardioplegia delivery set-up is rather complex and costly. Assuming that it was probably not the most appropriate under *normothermic* conditions, we have designed a simple, effective, and inexpensive delivery technique of normothermic continuous blood cardioplegia, which is described further herein.

Technique

Standard perfusion tubing (0.63 cm [2.5 inches] in diameter) is connected at one end to the top of the oxygenator and at the other end to the cardioplegia infusion catheter (Fig 1). This tubing passes through a separate roller pump, which allows delivery of cardioplegia at a controlled flow rate. The distal limb of the tubing (that is, the segment between the pump and the patient) incorporates a three-way stopcock, which is used for the delivery of our "mini" cardioplegic solution. Namely, this solution is made of 20 mL ampoules that contain only potassium

chloride (16 mEq per ampoule) and magnesium chloride (6 mEq per ampoule) in distilled water.

As soon as the ascending aorta has been cross-clamped, blood perfusion is initiated through the aortic root at a flow rate of 300 mL/min. Simultaneously, the full content of one ampoule is manually injected over approximately 30 seconds through the side port of the three-way stopcock. Cardiac arrest is achieved within 1 minute of aortic cross-clamping. As soon as the heart is arrested, the cardioplegia line is switched to a retrograde coronary sinus catheter and the flow rate of the pump is reduced to approximately 150 to 200 mL/min. An electrically driven syringe (Vial Medical, Grenoble, France) is then connected to the stopcock and allows the continuous delivery of cardioplegia during the remainder of the cross-clamping period. This syringe is filled with three of our cardioplegic ampoules, which represents a total volume of 60 mL. The rate of infusion is initially set at 45 mL/h because we have found that, on the average, this value allows us to keep the heart arrested. When there is a recurrence of electromechanical activity, the flow rate of the cardioplegia delivery syringe is transiently increased until activity ceases (we have gone up to 60 mL/h), except when the pattern of cardiac activity features "creeping" waves rather than rhythmic contractions, in which case a bolus of procaine (5 mL of a 1% solution) is more effective than an increase in potassium load. Once the heart is arrested again, the infusion rate is gradually brought back to its initial value. Whenever a stable asystole seems to have been achieved, attempts are made to progressively reduce the rate of infusion below the average value of 45 mL/h, and it is not uncommon that beyond approximately 30 minutes of aortic cross-clamping, an infusion rate in the range of 30 mL/h is effective in maintaining cardiac arrest (just as if an initially effective "impregnation" of the myocardium by the potassium-magnesium mixture allowed a reduction in the amount of cardioplegic agents subsequently required for maintaining cell depolarization).

Thus, for a 2-hour period of aortic occlusion, the volume of crystalloid cardioplegia delivered would be typically 65 mL (20 mL for induction and 45 mL for maintenance), which represents a total potassium load of 52 mEq (in fact, this load will often be less because, as previously stated, the infusion rate is itself frequently less than 45 mL/h during the last part of the procedure). Until now, hyperkalemia at the end of bypass has not been a clinical

Fig 1. Cardioplegia set-up.

cally relevant problem. Furosemide is only used when the urine output is inadequate.

Comment

Normothermic continuous blood cardioplegia is based on the observation that electromechanical work is the main determinant of myocardial oxygen requirements [1]. Consequently, the chemically induced abolishment of electromechanical activity, without added hypothermia, is expected to reduce metabolic needs to such an extent that they can be adequately matched by the continuous delivery of normothermic blood.

Because these residual metabolic needs cannot be predicted accurately in a given heart (and, in fact, most likely vary from one heart to another), it sounds logical to supply as much oxygen as possible to prevent the occurrence of an energy deficit and a subsequent anaerobic metabolism during arrest. In practice, optimization of oxygen supply can be achieved by maintaining a high flow rate of cardioplegia delivery (at least 150 mL/min when retroperfusion is used) together with a high oxygen content in the cardioplegic blood. The latter objective implies, in turn, that one should not dilute further blood that is already diluted by the pump prime, hence our concern about delivering a minimal volume of crystalloid cardioplegia by making up the cardioplegic "solution" with the sole additives that are likely to be critical in normothermic continuous blood cardioplegia, that is, the arresting agents.

The usefulness of the other usual components of cardioplegic solutions can be questioned in the setting of continuous perfusion with normothermic blood. Assuming that the preferred substrates of the heart are free fatty acids, glucose, and lactate [4], amino acid supplementation becomes debatable. Likewise, it is doubtful that artificial buffers (like tromethamine) or osmotic agents

provide protection beyond that due to the buffering and protein-based oncotic capacities of blood. A more important concern is the prevention of calcium overload, which can be enhanced by potassium-induced membrane depolarization [5]. To address this issue, we have used the natural calcium antagonist magnesium rather than the commonly used citrate-phosphate-dextrose chelating solution because magnesium could more effectively contribute to sustained asystole [5]. Limitation of the cardioplegic formulation to potassium and magnesium allows us to concentrate these ions in a small volume and, consequently, to virtually eliminate cardioplegia-induced hemodilution.

This technique has four attractive features: (1) It is simple. Perfusionists become rapidly familiar with the way of "playing" with the knob of the electrical syringe so that delivery of the smallest dose of cardioplegia can be conciliated with maintenance of arrest. From this standpoint, it seems at least as easy to handle a single cardioplegic formulation, the infusion rate of which is adjusted on-line, as to deliver alternatively two solutions differing by their potassium content. (2) It is effective in optimizing oxygen delivery as reflected by hematocrit values averaging usually 0.25, which has been shown to correlate with optimal preservation of normothermically perfused human hearts [6]. (3) It is inexpensive because apart from cardioplegia cannulas, the disposable delivery system only includes a single piece of tubing, a stopcock, and cardioplegia ampoules of simple formulation and, consequently, of low cost. (4) It is flexible as far as the temperature of the blood cardioplegic infusate is concerned because a separate heat exchanger can be easily incorporated in the cardioplegic circuit, thereby allowing one to meet an unexpected requirement for rapid cooling.

We acknowledge the active contribution of our perfusionists, Mrs Emmanuelle Baconnet, Maggy Devaux, Dominique Ponthier, and Mr Alain Bloquaux.

Autologous Pericardial Flap for Prevention of Reentry Injury in Cardiac Reoperations

Charles C. Canver, MD, Charles A. S. Marrin, MB, BS, Stephen K. Plume, MD, and William C. Nugent, MD

Section of Cardiothoracic Surgery, Dartmouth Medical School, Dartmouth-Hitchcock Medical Center, Lebanon, New Hampshire

Cardiac injury during sternal reentry to the heart is a rare but dangerous complication of cardiac reoperations. Positioning a pericardial flap between the heart and sternum at the time of the initial operation may consistently facilitate cardiac reoperation by providing a reliable plane of dissection and by reducing adhesion formation.
(*Ann Thorac Surg* 1993;55:179-80)

Epicardial and mediastinal adhesions are a reoperative challenge and can lead to serious problems, such as cardiac damage, catastrophic hemorrhage, and increased dissection time. To minimize the risk of complications during sternal reentry, the use of pericardial substitutes has been advocated [1-3]. However, in a recent survey 14% of surgeons reported that they were dissatisfied with these substitutes at reoperation [4]. A pericardial flap, the interposition of a pedicle of pericardium between the heart and sternum, has been shown to be a safe, simple, and effective means of preventing mediastinitis and sternal dehiscence after cardiac operations [5]. Since adopting the routine use of the pericardial flap technique in 1986, we have performed 13 reoperations in patients who had pericardial flap coverage during the primary cardiac operation. This report describes our experience with these operations and discusses the use of an autologous pericardial flap and its protective role during sternal reentry at the future cardiac reoperation. Our technique and results are described.

Technique

The pericardial flap technique used by us has been previously reported [5]. After a median sternotomy incision, the left pleural space is opened widely and, in most cases, the internal thoracic artery is harvested. The pericardium is opened at its junction with the diaphragm. The incision is made to the pleuropericardial reflection on the right, parallel to the diaphragm, and toward the ventricular apex on the left. The incision is then directed cephalad just lateral to, and following the course of, the left anterior descending artery to the level of the pulmonary artery. The pericardium and remaining mediastinal fat and thymic tissue are then divided as the incision courses ob-

liquely over the pulmonary artery to the aorta and along the inferior border of the innominate vein (Fig 1). The flap may be affixed to the right side of the sternal retractor by stay sutures or folded into the right chest while the operation progresses. If stay sutures are used along the left pericardial edge, care must be taken to avoid injury to the phrenic nerve.

Upon completion of the cardiac operation, separate mediastinal drainage catheters are placed in the posterior pericardial and left pleural spaces. Before the sternum is closed, the pericardial flap is placed over the right ventricle to ensure the presence of pericardial tissue between the heart and sternum. In the cases of myocardial revascularization, no effort was made to cover the left internal thoracic artery graft to the left anterior descending artery. To minimize the risk of pericardial tamponade and to promote the mediastinal drainage into the left pleural space, the pericardial flap was not sewn to any adjacent structures. After a successful resternotomy, the pericardial flap may be dissected from the undersurface of the left side of the sternum until the edge of the flap is

Fig 1. A prepared pericardial flap and its relationship to the other structures. (AO = aorta; PA = pulmonary artery; SVC = superior vena cava.)

identified and elevated off the epicardium. Appropriate operation may then be performed in the usual manner. The flap may also be reused at the completion of the reoperation if a future cardiac reoperation is anticipated.

Comment

We have performed cardiac reoperations in 13 patients who had undergone a primary cardiac operation with the use of a pericardial flap. Primary and repeat operations included coronary artery bypass grafting in 7 patients, aortic valve replacement in 4 patients, and mitral valve replacement in 2 patients. In all 7 patients having coronary artery bypass grafting, the left internal thoracic artery had been used as a graft to the left anterior descending artery during the primary cardiac operation. At reoperation, sternal reentry was established within a few minutes in all patients. Catastrophic hemorrhage and damage to the cardiac structures have not occurred in any of these patients. Epicardial and mediastinal adhesions were easy to dissect and were associated with decreased dissection time.

In summary, the routine use of a pericardial flap may consistently facilitate a cardiac reoperation. Fast and safe sternal reentry may reduce the operative time and may eliminate the risk of iatrogenic injury during resternotomy.

Use of Expanded Polytetrafluoroethylene Pericardial Substitute With Ventricular Assist Devices

William L. Holman, MD, Robert C. Bourge, MD, George L. Zorn, MD,
Linda H. Brantley, BS, and James K. Kirklin, MD

Divisions of Cardiothoracic Surgery and Cardiovascular Medicine, University of Alabama at Birmingham, Birmingham, Alabama

Expanded polytetrafluoroethylene membrane was used to reconstruct the pericardium after ventricular assist device insertion in 7 consecutive patients. One patient remains on support with the membrane in place and 6 have had the membrane removed. The expanded polytetrafluoroethylene membrane protected the device can-

nulas during repeat sternotomy and expedited the dissection of the heart and great vessels at the time of device removal. Reconstruction of the pericardium with expanded polytetrafluoroethylene membrane is recommended at the time of ventricular assist device insertion.

(*Ann Thorac Surg* 1993;55:181-3)

Ventricular assist devices (VADs) are currently used to support the circulation of critically ill patients until a donor heart becomes available or cardiac recovery occurs. We have noted that mediastinal adhesions become progressively more severe during the first several weeks after VAD insertion and prolong the dissection necessary when the VAD is removed. Expanded polytetrafluoroethylene (e-PTFE) pericardial substitute is recommended to minimize these adhesions and facilitate subsequent transplantation.

Technique

After completing VAD insertion a sheet of 0.1-mm e-PTFE membrane (Gore-Tex Surgical Membrane; W. L. Gore and Associates, Inc, Flagstaff, AZ) is placed between the pericardium and the epicardium laterally and between the VAD cannulas and overlying sternum anteriorly (Fig 1). The e-PTFE sheet is first placed between the right atrium and the pericardium, and the remaining portions of the membrane are tucked between the lateral and inferior surfaces of the ventricles and the pericardium. Mediastinal drainage tubes are left above and below the membrane, and interrupted monofilament sutures are used to secure the pericardial edges to the membrane. The VAD cannulas themselves are not wrapped with e-PTFE membrane. The sheet of e-PTFE should be placed over the heart in a position that minimizes creases and folds; however, no attempt is made to produce a watertight seal around the heart.

When the chest is reopened, the edge of the e-PTFE membrane is palpated immediately below the xiphoid process, and the plane between the membrane and the sternum is established. An oscillating saw is used to

divide the sternum, and the sternal fragments are dissected from the e-PTFE surface (Fig 2). The e-PTFE membrane is then lifted from the surface of the heart.

Results

Expanded polytetrafluoroethylene pericardial substitute has been used in 7 consecutive patients who required VAD support pending cardiac transplantation. As of July 30, 1992, one patient remained on support with the membrane in place. In the other 6 patients, the membrane was removed after a mean of 143 ± 39 days (range, 35 to 279 days). At re sternotomy, the e-PTFE membrane protected Dacron grafts to great vessels and the right ventricle from injury. The plane of dissection between the heart and the pericardium was visible after removal of the intact e-PTFE sheet (Fig 3).

Infection of the e-PTFE membrane occurred in 2 patients. Membrane infections developed in both of these patients after a second sternotomy, and both infected membranes cultured *Staphylococcus aureus*. In the first patient, a second sternotomy was required for relief of delayed tamponade. The e-PTFE membrane was removed 35 days later when fever and leukocytosis developed. This patient is currently well and is awaiting transplantation. In the second patient, the e-PTFE membrane became infected after a second sternotomy for transplantation. The transplant procedure was aborted due to acute procurement failure of the donor heart, and the e-PTFE membrane was left in place. This mediastinal infection remained indolent and was not confirmed until shortly before the patient's death. There were no other membrane-related complications.

Comment

Insertion of a VAD as a bridge to cardiac transplantation commits the patient to a second sternotomy. Donor avail-

Accepted for publication Sep 23, 1992.

Fig 1. In this view from the patient's head, the expanded polytetrafluoroethylene membrane is seen in place over the heart and cannulas for a left ventricular assist device.

ability is uncertain, and in our recent experience waiting periods of several months are common. Adhesions that form during the waiting period can prolong the transplantation procedure and increase blood loss, particularly if the patient is maintained on therapeutic levels of anticoagulation. Dense adhesions between the graft(s) and overlying sternum pose a special risk for serious hemorrhage at reoperation. Thus, the use of a pericardial substitute seems worthwhile.

Investigators at the University of Utah have suggested using glutaraldehyde-fixed pericardium to facilitate reoperation after implantation of a total artificial heart [1]. However, reports of dissatisfaction with bovine pericardial substitute in humans [2] persuaded us that e-PTFE membrane would be a better choice. Studies in animals [3], as well as experience with e-PTFE membrane in humans [2, 4], have shown that fibrous adhesions to the e-PTFE membrane are mild and calcification does not occur. Epicardial thickening occurs in reaction to the e-PTFE membrane and can obscure coronary anatomy, but this is of little importance before transplantation. Our own clinical experience supports the use of the e-PTFE membrane at the time of VAD implantation to increase the safety of reoperation and the ease of subsequent dissection at the time of transplantation.

There is a risk of infection when any foreign material is

Fig 2. At resternotomy for cardiac transplantation, the expanded polytetrafluoroethylene membrane protects the right ventricle and Dacron conduits from injury. The expanded polytetrafluoroethylene membrane also facilitates dissection of the heart from the pericardium.

left in the body. The incidence of infection for e-PTFE membrane used to reconstruct the pericardium after other cardiac operations is low [2, 4], whereas the incidence of infection related to VAD use is higher [5]. It is possible

Fig 3. Expanded polytetrafluoroethylene membranes that are in place for several weeks become translucent but retain structural integrity and can be removed intact from the mediastinum at the time of transplantation.

that the presence of an e-PTFE membrane increases the risk for mediastinal infection after VAD insertion. However, note that in the 7 patients of this study e-PTFE membrane infections only occurred after a second operation, and one of these two infections was successfully managed by removal of the membrane with antibiotic therapy. Clearly, meticulous sterile technique is essential when a VAD or an e-PTFE membrane is placed in the chest, and continued monitoring of infectious complications in these patients is indicated. If signs of infection occur, membrane- or VAD-related infections must be suspected and aggressively treated.

This work was performed during Dr Holman's tenure as an Established Investigator for the American Heart Association.

Naming the Bronchopulmonary Segments and the Development of Pulmonary Surgery

Will C. Sealy, MD, Samuel R. Connally, PhD, and Martin L. Dalton, MD

Department of Surgery, Mercer University School of Medicine and Medical Center of Central Georgia, Macon, Georgia

An international agreement on bronchial nomenclature and anatomy was not reached until well after operations for bronchopulmonary segmental disease were well developed. R. C. Brock, in 1950, was the reporter of the efforts of The Thoracic Society of Great Britain to bring some order to this confused state. This Society delayed its action until an ad hoc committee made up of members from other countries and specialties met at the International Congress of Otorhinolaryngology in 1949. The

anatomy and nomenclature of the bronchopulmonary segments was agreed upon. The Thoracic Society then accepted the report of the ad hoc committee. The system was followed closely by the first *Nomina Anatomica* in 1955. This report did not open new surgical vistas but was the marker indicating that pulmonary surgery was now mature.

(*Ann Thorac Surg* 1993;55:184-8)

By the mid-1900s the practice of excisional pulmonary surgery had become progressively more selective in preserving pulmonary tissue by substituting lobectomy for pneumonectomy in many malignancies and segmentectomy for lobectomy in infections and other segmental diseases. In spite of this remarkable progress, the anatomy and the nomenclature of the bronchopulmonary segments were not clearly established. In 1949, The Thoracic Society of Great Britain recognized this problem and initiated a move that led to the significant report by Russell C. Brock, "The Nomenclature of Bronchopulmonary Anatomy: An International Nomenclature Accepted by The Thoracic Society" [1]. This recommendation became widely accepted and was only slightly modified in the *Nomina Anatomica* in 1955 and the years following. This consensus statement did not suddenly open new vistas to the thoracic surgeon, but was, in fact, an indicator that lung surgery had reached its zenith and was based on sound anatomic facts.

In the first quarter of the century, anatomic atlases, texts, and descriptions of the segmental bronchi were not portrayed in any detail. For example, *Morris's Human Anatomy* [2] and Werner Spalteholz's *Hand Atlas of Human Anatomy, 7th Edition* [3], showed excellent metal casts of the bronchial tree but contained no accompanying segmental detail. *Eparterial* was the descriptive term for the right upper lobe because of its course above the pulmonary artery. *Hyperarterial* was the term used for the middle and lower bronchi. The segments were described as arising alternately anteriorly and posteriorly, from the bronchus. These designations stemmed from Aebey's work, a study in comparative anatomy, which has been summarized by Huntington [4] and Boyden [5].

The concept of a defined segment of lung leading into a

specific bronchial branch was originated by Ewart [6], a pathologist at the Brompton Hospital in London. He described the bronchi as being distributed to specific pulmonary districts. In 1932, two American nose and throat surgeons, Rudolph Kramer and Arael Glass [7] of New York, agreed with this concept but suggested the term *bronchopulmonary segment* be assigned to the districts. They proposed a system of nomenclature, noted the relationship of the lung segments to the chest cage as shown on x-ray films, and suggested how this information might be used in treating lung abscesses.

The confused state of the nomenclature together with the anatomy of the bronchopulmonary segments in the years just before Brock's report are illustrated by a publication in 1942, "War Injuries of the Chest" [8]. This was edited by H. Morriston Davies and Robert Coope and was intended for use by the military and civilian casualty surgeons in Great Britain (Fig 1). Note that an axillary segment is represented by a circular opening in the upper lobe bronchus. This was often considered to be a separate segment that extended directly to the axilla and was thus viewed end-on in the lateral x-ray films. It is, in fact, the right upper lobe bronchus. The axillary portions of the upper lobes are normally supplied by two subsegments as shown in Figure 2. Also note that on the left, a middle lobe seems to arise from the left main bronchus. Among other reports in the English language, with variations in nomenclature and anatomy, are those of Adams and Davenport [9], Nelson [10, 11], Neil, Gilmour, and Gwynne [12], Appleton [13], and Foster-Carter [14]. Many of these studies illustrated their observations with bronchograms.

Two reports appeared in the early 1940s that had a profound impact on the establishment of the nomenclature and descriptions of segmental bronchopulmonary anatomy. The first originated in the United States, the second from Great Britain. Bronchoesophagology became a well-developed subspecialty of otorhinolaryngology in

Address reprint requests to Dr Sealy, Department of Surgery, Mercer University School of Medicine and Medical Center of Central Georgia, Macon, GA 31208.

Fig 1. The segmental bronchi shown in the lateral projection, right number 4, left number 5. This appeared in "War Injuries of the Chest" published in Great Britain in 1942. Note that there are additional segments (axillary) shown in the upper lobes. The axillary bronchus was thought to extend in a straight lateral direction to the axillary area. This is, in fact, the right upper lobe orifice. The lingula appears to arise from the left main bronchus and is called the middle lobe. No medial basal segment is shown on the right or left. The exact origin of the nomenclature is not given. (Reprinted from Davies HM, Coope R, eds. War injuries of the chest, Edinburgh, E & S Livingstone, 1942:4, 5, with permission.)

the first half of this century, and its practitioners were concerned with the identification of segmental bronchial orifices and their relationship to the appropriate lung segments and their projection on x-ray films. Chevalier L. Jackson, a bronchoesophagologist, and John F. Huber, an anatomist, both of Philadelphia, accurately described the anatomy and proposed a simple system of nomenclature for the bronchopulmonary segments. This was published

in *Diseases of the Chest* in 1943 [15]. Their system of nomenclature is still closely followed by the *Nomina Anatomica* (Table 1). This was the only report of their work other than a paper by Huber in 1949 [17]. Jackson and Huber [15] explained the need for their studies by the following: "In any event we feel that the time has come when every bronchoscopist, certainly every bronchologist, must think in terms not of lobar bronchi or of lobes, but also segmental bronchi and broncho-pulmonary segments . . ."

In an effort to obtain precise information concerning the bronchopulmonary segments, which could be applied to the surgical treatment of lung abscesses and other lung infections, Russell C. Brock in England carried out extensive dissections with elegant reconstructions of the bronchopulmonary segments, lobes, and lungs. He related the findings to chest roentgenograms and bronchograms. He first published his observations in a series of articles in *Guy's Hospital Reports* starting in 1942, and then com-

Fig 2. The anatomy and recommended nomenclature of the segmental bronchi proposed by the International Committee in 1949. The numbers refer to the names listed in Table 2. Note that a medial basal segment, number 7, is not shown on the left. The subsegments in the upper lobes shown on the right anterior and posterior segments and the left anterior segment are distributed to the axillary area. Singling out these subsegments may have been due to the fact that many believed that there was a separate segmental bronchus to the axillary area. The question of the name of the right bronchus between the upper and middle lobes was settled by calling it the lower part of the right main bronchus instead of bronchus intermedius. (Reprinted from Brock RC. The nomenclature of broncho-pulmonary anatomy: an international nomenclature accepted by The Thoracic Society. *Thorax* 1950;5:224, with permission.)

Right	Left
Right upper lobe bronchus	Left upper lobe bronchus
I Apical	I, II Apico-posterior
II Posterior	
III Anterior	III Anterior
Middle lobe bronchus	
IV Lateral	IV Superior lingula
V Medial	V Inferior lingula
Right lower lobe bronchus	Left lower lobe bronchus
VI Superior	VI Superior
VII Medial basal (cardiac)	VII Medial basal (cardiac)
VIII Anterior basal	VIII Anterior basal
IX Lateral basal	IX Lateral basal
X Posterior basal	X Posterior basal

^a The 1989 *Nomina Anatomica* nomenclature [16] of the bronchial tree is now like that of Jackson and Huber except for separating antero-medial into anterior and medial to denote two of the basal segments.

bined the studies in a monograph published in 1950 entitled "The Anatomy of the Bronchial Tree With Special Reference to Surgery of Lung Abscesses" [18]. A second edition [19] appeared in 1954 in which the ad hoc International Committees' nomenclature was used. These studies became the models of surgical anatomic research. The senior author was fortunate enough to have seen the superb models used to illustrate Brock's papers at the Brompton Hospital in 1944.

In 1945, Edward A. Boyden [20], a member of the Department of Anatomy at the University of Minnesota, first became aware of the problem facing the surgeon in performing segmental resections. He described this as follows: "This article is an outgrowth of a surgical staff conference in which the author was asked by Dr. Owen H. Wangenstein to discuss the anatomy of the segmental pneumonectomy. Search of the literature having failed to yield any comprehensive figures of dissection of the external and the interlobar surfaces of the lung, the author was obliged to make preliminary dissections. The present article is an attempt to remedy that defect in the literature." Boyden [5] adapted the nomenclature of the bronchi proposed by Jackson and Huber, and included extensive dissections of the vascular supply of the lobes and segments, using a numbering system for all the elements. His work showed the relationship of the vascular anatomy with the bronchial anatomy, thus completing the map the surgeon needed for segmental resections.

Well before Brock's report on the nomenclature of the bronchopulmonary segments, surgeons were developing procedures for their removal. Edwin Churchill and Ronald Belsey [21], in 1939, reported their method for lingular and basal segmental resections for bronchiectases, and thus emerged the concept of segmental resection as a means of preserving functioning pulmonary tissue. A report by Brian Blades [22] on removing basal segments appeared in 1943. In 1947, Richard Overholt and Lazaro Langer published a significant article, "A New Technique for Pulmonary Segmental Resection. Its Application in the Treatment of Bronchiectasis" [23]. Details were given on the treatment of 21 patients. The segments removed were the lingula and the basal segments and the anterior segment of the right upper lobe. The authors stressed the use of blunt dissection. In 1947 Gordon Scannell [24] reported his experience with resection of the medial basal segment of the lower lobe of the right and the anterior segment of the left upper lobe. He continued his work in the laboratory with Boyden on segmental anatomy [25, 26]. Beatty Ramsay, in 1949, described the importance of the segmental veins as guides to the intersegmental plane [27].

The need for a clear definition of the anatomy and an accepted system of nomenclature was now critical, for surgery for segmental disease was well established. To remedy this problem, at least in Great Britain, The Thoracic Society in May of 1949 formed a committee made up of R. C. Brock (a surgeon), A. F. Foster-Carter (a physician), A. B. Appleton (an anatomist), and V. E. Negus (a nose and throat surgeon) [1]. Just before the committee completed its report, it learned that Professor E. Huizinga of the Netherlands had requested that an ad hoc interna-

tional group be formed to consider this same problem at the forthcoming International Congress of Otorhinolaryngology meeting in July 1949 in London. The Thoracic Society therefore tabled their study, believing that action by this group would more likely lead to the worldwide acceptance of the system.

The International Committee was composed of 15 members. Among them were Brock, Negus, Appleton, and T. Nicol of The Thoracic Society of Great Britain and four bronchoesophagologists, Chevalier L. Jackson, Paul Holinger, Louis Clerf, and Gabriel Tucker, the only members from the United States. This representative committee agreed that the system adopted should be simple and easily translatable into different languages, and that it should conform to established knowledge and descriptions of anatomy. Each bronchopulmonary segment would receive a number. The part of the lungs supplied by the segmental bronchus would be given the name of the segmental bronchus.

The committee considered five systems of anatomy and nomenclature [1]. These were submitted by Brock, Foster-Carter, Jackson and Huber, Huizinga, and Kourisky, the latter being from France. The greatest problem was nomenclature, for the anatomic descriptions in the five systems differed in only a few minor details (Table 2). However, there was disagreement about the status of the medial basal segment on the left as a separate segment. Jackson and Huber combined the medial and the anterior basal segments, naming them the anterior-medial basal segment, and noted that they arose from a single branch of the lower lobe bronchus. One question posed was whether apical, used by Brock, or superior, used by Jackson and Huber, would designate the first segment of the lower lobe. Apical was accepted at the expense of superior. Brock's middle basal segment was changed to lateral basal segment. Figure 2 shows the anatomy of the bronchial tree agreed upon. The conclusions of the International Committee were accepted by The Thoracic Society. R. C. Brock recorded this event in *Thorax* in 1950 [1]. This international accord resolved the major disagreements in bronchopulmonary segmental anatomy and presented a reasonable system of nomenclature that served until the publication of the first *Nomina Anatomica* in 1955 [28]. The latter followed The Thoracic Society's report very closely, using apical for superior to designate the first segment of the lower lobe, and including the subapical segment of the lower lobe as described by Brock. The latter was in parentheses, designating it as acceptable but not recommended. In the recent *Nomina Anatomica* [16] superior has replaced apical, subapical has been deleted, and medial basal segment is included (see Table 1).

The series of events defining the anatomy and leading to a widely acceptable nomenclature of the bronchopulmonary segments confirms the over-used expression: "Necessity is the mother of invention." This orderly progression, delineating the precise anatomy of the bronchopulmonary segments, began with the bronchoscopist's need to know where the segmental bronchi originating from the orifices, noted in the bronchoscope, were distributed. The surgeon needed to be able to determine

Table 2. The Nomenclature Adopted by the Ad Hoc International Committee Meeting at the Time of the International Congress of Otorhinolaryngology in 1949 [1]*

International Nomenclature	Brock	Jackson and Huber
Right upper lobe bronchus		
Apical (1)	Pectoral	Anterior
Posterior (2)	Subapical	Posterior
Anterior (3)	Apical	Apical
Middle lobe bronchus		
Lateral (4)	Lateral	Lateral
Medial (5)	Medial	Medial
Right lower lobe bronchus		
Apical (6)	Apical	Superior
Medial basal (cardiac) (7)	Cardiac	Medial basal
Anterior basal (8)	Anterior basal	Anterior basal
Lateral basal (9)	Middle basal	Lateral basal
Posterior basal (10)	Posterior basal	Posterior basal
Left upper lobe bronchus		
Upper division	Apicopectoral	Upper division
Apical (1)	Apical	Apical
Apicoposterior 1 and 2	...	Apical-posterior
Posterior (2)	Subapical	Posterior
Anterior (3)	Pectoral	Anterior
Lingula	Lingula	Lower (lingular) division
Superior (4)	Upper	Superior
Inferior (5)	Lower	Inferior
Left lower lobe bronchus		
Apical (6)	Apical	Superior
Anterior basal (8)	Anterior basal	Anterior medial basal
Lateral basal (9)	Middle basal	Lateral basal
Posterior basal (10)	Posterior basal	Posterior basal

* Two of the five systems, those of Brock and Jackson and Huber, are included. The problem of the presence of a medial basal segment on the left was not resolved and omitted entirely. Brock's apical instead of Jackson's and Huber's superior was adopted for the first branch of the lower lobe.

the precise location of lung abscesses and other inflammatory disorders for successful treatment. The importance of confining resections just to the diseased part of the lobe became paramount as indications for lung surgery broadened.

The publication in 1950 by The Thoracic Society of Great Britain of the report of the ad hoc International Committee that provided an accurate description of the anatomy and a reasonable nomenclature of the bronchopulmonary segments was a marker of the maturing of thoracic surgery that peaked in the 1950s. The reporter of this agreement, Russell C. Brock, was responsible for much of its anatomic accuracy. His meticulous anatomic dissections and detailed preparation of illustrative material represents a paradigm of surgical anatomic research. It was fitting that Brock was the recorder of the occasion indicating that lung surgery had now reached the zenith of its development.

Solitary Squamous Cell Papilloma of the Trachea

Yoshifumi Naka, MD, Kazuyasu Nakao, MD, Yasumasa Hamaji, MD,
Masaaki Nakahara, MD, Masahiko Tsujimoto, MD, and Kazuya Nakahara, MD

Departments of Surgery and Pathology, Osaka Police Hospital, and First Department of Surgery, Osaka University Medical School, Osaka, Japan

We report a case of solitary squamous cell papilloma of the trachea and review 55 other previously reported cases. A 69-year-old man was admitted to our hospital with hemoptysis. Bronchoscopy demonstrated a papillomatous tumor diagnosed as a squamous cell papilloma. A circumferential resection of the trachea with end-to-end anastomosis was carried out. The patient's postoperative course was uneventful. From the review, there

seems to be no considerable difference in the prognoses between the endoscopically and surgically managed groups. The following indications for surgical management of solitary tracheobronchial papilloma are proposed: (1) wide-based tumor, (2) poorly visualized tumor by endoscopy, (3) suspicion of malignant tumor, and (4) patients not suitable for long-term follow-up.

(*Ann Thorac Surg* 1993;55:189-93)

Squamous papilloma is the most common benign tumor of the larynx. In contrast, solitary squamous cell papilloma arising in the tracheobronchial tree is quite rare. In this report, we describe a case of solitary tracheal papilloma that was managed by a circumferential resection of the trachea, and we review 55 other cases of solitary tracheobronchial papilloma previously reported.

Case Report

A 69-year-old man was admitted to our hospital with 4 months of hemoptysis and pharyngeal pain. During this period, he reported coughing up "a bulky, scab-like object." He smoked 20 cigarettes a day for 50 years and had pneumonia at 65 years of age. The chest roentgenogram revealed an opacified lesion protruding into the trachea just above the carina. Cytologic examination of the sputum demonstrated class III squamous metaplastic cells. A tomogram of the trachea showed an exophytic lesion above the carina. A computed tomographic scan showed a tumor shadow at the posterior, right wall of the trachea. Neither intrapulmonary tumors nor mediastinal lymphadenopathy were noted. Bronchoscopy demonstrated a papillomatous, wide-based tumor at the posterior right wall of the trachea, 6 cm below the vocal cords. The tumor was diagnosed as a squamous cell papilloma on histological study of the biopsy specimen.

An operation was performed through a right thoracotomy (Fig 1). The trachea was opened distal to the tumor, just above the carina, and then the left and right lungs were ventilated by an endotracheal tube and jet-ventilation catheter, respectively. We carried out a circumferential resection of the trachea including six tracheal rings with an end-to-end anastomosis. The intraoperative histological examination of the margins of the resected specimen revealed no residual tumor cells. The patient

was discharged 1 month postoperatively. His course was uneventful and he remains in good health 18 months later.

The papilloma in the right wall of the trachea was a cauliflower-like and wide-based tumor with a diameter of 22 mm at its base and a height of 7 mm (Fig 2). On microscopic examination the tumor consisted of numerous papillomatous fronds. All of these fronds were lined by hyperplastic, squamous epithelium showing moderate parakeratosis and hyperkeratosis (Fig 3). Neither carcinoma in situ nor atypia was present. The tumor was diagnosed as a solitary, squamous papilloma of the trachea. An immunohistochemical examination did not demonstrate papilloma virus infection in the specimen.

Comment and Review

Squamous cell papillomatosis is the most common benign tumor of the larynx and may spread to affect the tracheobronchial tree. In contrast, solitary squamous cell papilloma arising in the tracheobronchial tree is quite rare. We review 56 cases of solitary papilloma that have been reported in the English-language literature, including our own case. These are summarized in Table 1 [1-29]. The age of the patients ranged from 1.5 to 75 years, with the average age being 51.4 ± 15.8 years, older than that of patients with laryngobronchial papillomatosis. Forty-one patients were male and 9 were female; the sex of 6 was unknown. Papillomas were located in a lobar bronchus in 41 patients, a main bronchus in 7, the trachea in 5, and an unknown location in 3. Solitary papilloma of the trachea as well as squamous cell carcinoma of the trachea is very rare [30]. Most of 56 patients whose cases we reviewed were heavy smokers; smoking is thought to be one of the most likely causes of solitary papilloma. In our case, the patient was a heavy smoker and papilloma virus infection was not demonstrated in the resected specimen by immunohistochemistry.

CXR = chest roentgenogram; IB = intermediate bronchus; L = left; LLLB = lower lobe bronchus; MB = main bronchus; NM = not mentioned; right; SCC = squamous cell carcinoma; T = tumor; Tbc = tuberculosis; Tr = trachea; ULB = upper lobe bronchus.

MLB = middle lobe bronchus; R =

Fig 1. Schema of the operative method. (JV = jet ventilation catheter.)

In 48 cases of bronchial papilloma, pneumonectomy was performed in 4 patients, lobectomy in 23, resection of the tumor in 2, circumferential resection of the bronchus in 1, endoscopic removal in 5, and miscellaneous procedures in 3. In 5 cases of tracheal papilloma, 1 surgical resection, 2 circumferential resections of the trachea (including our case), and 1 endoscopic removal were performed; the fifth patient with tracheal papillomas died

Fig 2. Macroscopic view of the circumferentially resected trachea with a solitary papilloma.

Fig 3. Microscopic view of the resected specimen. (Top) Papillomatous processes are lined by feebly keratinized squamous epithelium. (Hematoxylin and eosin, low magnification). (Bottom) The squamous epithelial lining of the papillary processes shows mild dysplasia but no malignancy. (Hematoxylin and eosin, high magnification).

suddenly during observation. The procedures performed in 3 patients are not known. As shown in Table 2, endoscopic therapy has become more frequent, although surgical management was employed in more than half of the cases in the new era. Approximately half of all cases between 1980 to 1990 [14-29; present our case] were managed endoscopically. We expect that as endoscopic therapy improves, more of these tumors will be managed endoscopically in the future.

In terms of prognosis, defining recurrence and death of any cause after surgical or endoscopic management as the postmanagement events, there were 4 events (2

Table 2. Changes in Management^a

Era	Endoscopic Therapy	Surgical Management	Miscellaneous
Old era (1954-1979)	4	18	4
New era (1980-1991)	13	14	1

^a Difference between old era and new era: $p < 0.05$ by χ^2 test.

Fig 4. Actuarial event-free rate of the endoscopically and surgically managed groups. There was no significant difference between the groups.

deaths due to cancer and bronchial hemorrhage and 2 recurrences) in 16 surgically managed patients and 3 events (2 deaths due to perforation of duodenal ulcer and lung cancer and 1 recurrence) in 14 endoscopically managed patients. In addition, there is no significant difference in the event-free rate between the endoscopically managed group and the surgically managed group (Fig 4). This suggests that endoscopic therapy is as effective as operation.

In our case, we initially debated whether to perform endoscopic or surgical resection of the tumor. However, the tumor was wide-based and therefore seemed poorly suited for endoscopic extirpation. We have performed more than 30 circumferential resections of the trachea for thyroid cancer invading the trachea without any serious tracheal complications. Grillo and Mathisen [31] reported that primary tracheal tumors were able to be safely managed by the tracheal resection with primary reconstruction. Therefore, we felt comfortable in electing to perform a circumferential resection with end-to-end anastomosis to obtain a sufficient margin.

If a tracheal tumor is malignant, tracheal resection is necessary. However, nonsurgical and endoscopic management is recommended if the tumor is benign, its location seems suited for endoscopy, and repeated therapy is possible. We, therefore, propose the following indications for surgical management of solitary papilloma arising in the tracheobronchial tree: (1) the tumor is wide-based; (2) endoscopic therapy is difficult because the tumor is located in an area where it is poorly visualized; (3) it is suspected that the tumor is malignant on histological examination; and (4) it is difficult to carry out long-term follow-up of the patient, whether due to economic, geographic, or psychological problems. In our patient, surgical management was indicated by the first criterion. He underwent a circumferential resection of the trachea with end-to-end anastomosis. His postoperative course has been uneventful.

Retrograde Warm Blood Cardioplegia

To the Editor:

As the lead author of the article entitled, "Retrograde continuous warm blood cardioplegia: a new concept in myocardial protection" [1], I would like to bring to the attention of the readership of *The Annals of Thoracic Surgery* an overlooked study by Gott and associates in 1957 [2]. In this experimental study, Gott and associates combined retrograde continuous blood perfusion with potassium citrate (Melrose's solution)-induced cardiac asystole to reduce myocardial oxygen demands and extend the safe duration of retrograde blood perfusion. They demonstrated that the mortality of dogs undergoing retrograde blood perfusion for 30 minutes was reduced by 50% if blood cardioplegic arrest was induced simultaneously. "On the basis of these experimental studies . . . the combination of retroperfusion and potassium asystole appears valuable for precise, direct vision reparative procedures upon the aortic valve or coronary arteries in a quiescent operative field" [2].

Hence, it appears to me that the concept of retrograde continuous normothermic blood cardioplegia and the underlying framework of what is now called "warm heart surgery" is, in fact, not new and should be properly credited as an evolution of the pioneering work of Dr Lillehei's group.

Reply

To the Editor:

Doctor C. Walton Lillehei and I appreciate the foregoing letter from Dr Salerno to the editor regarding our use, in 1957, of combined retrograde coronary blood perfusion in combination with potassium citrate cardioplegia [1].

I had the good fortune of working as a research fellow in Dr Lillehei's cardiac surgical laboratory from the fall of 1955 through 1956. With the availability of the DeWall-Lillehei bubble oxygenator in the summer of 1955, Lillehei and his team were ready to attempt direct-vision repair of the diseased mitral valve and aortic valve, something that had not been feasible with cross-circulation. We initially evaluated, in the canine preparation, continuous antegrade perfusion using coronary cannulas, but this had the obvious disadvantage of partially obscuring the operative field and, also, the possibility of coronary ostial damage.

We became aware that Pratt [2] in 1898 had been able to support the excised cat heart for a few minutes with retrograde perfusion. Also, Blanco and associates [3] had reported on successful support of the canine heart for up to 7¼ minutes using retrograde perfusion.

After working on the technique of warm retrograde perfusion in the animal laboratory for several months, Dr Lillehei and his operative team used this technique on the first individual to have direct-vision operative repair for aortic stenosis at the University of Minnesota Hospital. At the time of this patient's operation (January 31, 1956) a small separate pump was set to deliver 125 mL of oxygenated blood per minute, and a direct-vision aortic valve commissurotomy was carried out with debridement of calcium from the valve. The total duration of the cardiopulmonary bypass run was 15¼ minutes, and the myocardium was nourished for 11 minutes by retrograde coronary perfusion. This patient made an uneventful recovery; her class IV functional status was converted to class II.

Between January 31, 1956, and April 13, 1956, Dr Lillehei and his team used warm continuous retrograde perfusion in 7 patients at the University of Minnesota [4]. In addition to the first patient who had the successful repair of a stenotic aortic valve, 2 more patients underwent successful aortic valvulotomy; a fourth patient died 2 days postoperatively of apparent aortic insufficiency. Three children had retrograde perfusion for congenital defects: a 10-year-old girl had a ruptured sinus of Valsalva successfully repaired, a 7-month-old girl had a successful correction of an aorticopulmonary window but died 10 days postoperatively of diffuse bronchiolitis obliterans, and a 2-year-old child underwent an attempted arterial switch of transposition of the great vessels. Retrograde perfusion was used for 16 minutes during the 1 hour 11 minute heart-lung bypass with the pump oxygenator. Heart action was excellent during bypass and at the conclusion of the operation, but the patient died in the early postoperative period of indeterminate causes.

We determined in the research laboratory that retrograde perfusion was successful in supporting the canine heart for periods of 15 to 20 minutes. However, of 4 animals submitted to 30 minutes of retroperfusion, 3 died, apparently of irreversible fibrillation. We thought that we might be able to extend the myocardial protection beyond 30 minutes if we combined retroperfusion with asystole induced with Melrose's potassium citrate solution. As Dr Salerno indicated in his letter, the combination of potassium citrate asystole with 30 minutes of retrograde perfusion allowed for an 80% survival among 10 animals versus 60% survival in 10 animals that received 30 minutes of retroperfusion alone [1]. Interestingly, there was only a 10% survival among 10 animals who had 15 to 30 minutes of potassium citrate asystole. It is important to note, though, that the Melrose potassium citrate solution used, both experimentally and clinically in the mid-1950s, was about ten times more concentrated than Gay-Ebert solution and, therefore, had its own inherent detrimental effect.

It has been interesting to see a great deal of current interest in retrograde perfusion. This has been a logical extension of antegrade blood cardioplegia, both cold and warm. Interestingly, among the 448 abstracts recently submitted for consideration for presentation at the 1993 meeting of The Society of Thoracic Surgeons, there were 22 that dealt with newer techniques of myocardial protection. Half of these were clinical reports and the other half were from the research laboratory. The majority of the 22 reports on myocardial preservation dealt with comparison of various combinations of antegrade blood cardioplegia, both cold and warm, and retrograde cardioplegia, both cold and warm. The fact that there were so many abstracts submitted on this subject would indicate to me that many cardiac surgeons are still not totally pleased with their method of myocardial protection.

In 1974 we initiated, at The Johns Hopkins Hospital, standard intermittent crystalloid cardioplegia as recommended by Gay and Ebert [5]. In 1982 we added the significant protection factor of Stanford topical cold-saline pericardial perfusion (14 to 16 L used

during a standard triple bypass procedure). We continue to favor crystalloid cardioplegia because of its simplicity and seemingly excellent myocardial protection. We, however, seem to be, from the standpoint of myocardial protection techniques (ie, blood versus crystalloid, retrograde versus antegrade), very much in the minority.

Again, Dr Lillehei and the rest of his research and clinical team appreciate Dr Salerno's letter on this topic of retrograde coronary perfusion.

White Matter Lesions and Heart Operations

To the Editor:

I read with interest the article by Sellman and associates [1] concerning magnetic resonance imaging of the brain. The attention to white matter lesions has been stimulated recently by reports of low density in the periventricle on x-ray computed tomographic scan [2, 3] and high signal intensity on T₂-weighted magnetic resonance imaging [4-6]. However, to our knowledge, no investigator had described the patients selected for cardiac operation who had cerebral white matter lesions. Diffuse white matter lesions are assumed to be caused by an increase in cerebral vulnerability due to harmful effects of cardiopulmonary bypass. We conducted a clinical study to define the relation between coexistent diffuse cerebral white matter lesions and neuropsychological outcome after coronary artery bypass grafting.

X-ray computed tomographic scan of the brain was performed in 104 patients, and preoperative and postoperative neuropsychological functions were evaluated. The average age was 66.8 years (range, 54 to 80 years). The patients were categorized as follows according to the computed tomographic findings: 73 patients were normal or showed slight cerebral cortical atrophy, which is usually seen in patients more 50 years of age (group 1); 16 patients showed moderate or severe cortical atrophy (group 2); and 15 patients demonstrated severe white matter hypodensity especially in the frontal horns, and dilated ventricles (group 3). Fourteen of 15 patients in group 3 were hypertensive. No patient showed neurological signs or psychiatric abnormalities at preoperative clinical examination. The anesthetic regimen used was based on a modified form of neuroleptanalgesia supplemented by muscle relaxants. Extracorporeal circulation was accomplished with pulsatile flow, and a Mera membrane oxygenator was employed. Moderate systemic hypothermia (30°C) was induced. The flow rate of the extracorporeal circulation was maintained at 2.0 to 2.5 L/m². The duration of cardiopulmonary bypass time

was 161 ± 39 minutes, and the aortic cross-clamp time was 76 ± 16 minutes. No significant difference was noted between the groups in terms of patient's age, duration of cardiopulmonary bypass, and perioperative blood pressure.

Clinically overt neuropsychological deterioration was not observed in patients in groups 1 and 2. Six patients in group 3 presented psychiatric disturbance in the form of intellectual impairment, states of confusion, and alteration of personality immediately after coronary bypass operation. A pseudobulbar palsy was also observed in 3 patients. These clinical signs of neuropsychological impairment persisted for 1 to 3 weeks, and were most often reversible.

The underlying mechanism of these deleterious alterations is not elucidated, but the ischemic nature of the characteristic white matter lesions is suspected. The periventricular area is an end zone for perforating arteries arising from the surface cerebral arteries, and large white-matter lesions in deeper white matter were associated with a diffuse decrease of cortical perfusion [7]. We assume that the arteriosclerotic changes of the long cortical perforating arteries led to inadequate cerebral cortical perfusion during cardiopulmonary bypass, which is a major cause of neuropsychological dysfunction. Computed tomographic scan has proved less sensitive than magnetic resonance imaging in detecting white matter lesions, and the number of patients in our series was small [4]. This problem should be further assessed with a more detailed analysis of both cerebral cortical lesions and neuropsychological findings.

Reply

To the Editor:

My colleagues and I appreciate Drs Iguchi and Sato's comments regarding our article about cerebral magnetic resonance imaging findings after coronary artery bypass grafting. White matter lesions were observed in 17 of our 29 patients (59%) and were not altered by extracorporeal circulation. Our patients were on aver-

age 7 years younger (mean, 60 years; range, 45 to 69 years) than those of Drs Iguchi and Sato. As white matter abnormalities are supposed to be related to aging, we find their 14.4% (15/104 patients) incidence of lesions low. Are we discussing identical white matter lesions or are there considerable variations? In contrast to Drs Iguchi and Sato, we did not correlate white matter lucencies to postoperative neuropsychological findings. We agree that magnetic resonance imaging is superior for detecting ischemic complications after extracorporeal circulation compared with computed tomography.

We plan further investigations with a so-called diffusion magnetic resonance imaging technique to detect ischemic areas during extracorporeal circulation, and also to functionally map these patients with a positron emission tomograph and simultaneous neuropsychological testing.

"Chordal" Preservation During Mitral Valve Rereplacement

To the Editor:

Olinger [1] recently described a method for "represerving" the mitral subvalvular apparatus during rereplacement of a failed mitral bioprosthesis that had originally been inserted with preservation of the mitral leaflets and chordae.

Although I strongly support and practice the principle of chordal preservation during mitral valve replacement, the elegant technique described by Olinger for rereplacements seems rather time consuming, and it is not feasible if—as is so often the case—the first operation was carried out without chordal preservation.

A simpler, equally effective, and more expeditious technique for maintaining the normal relationship between the mitral annulus and the papillary muscles has been advocated by Tirone David, MD, for several years, and I have used it many times. It is particularly helpful for rereplacements, although it is also quite suitable for initial replacements whenever preservation of the native valve is awkward or impractical, such as in patients with calcific rheumatic mitral disease.

In brief, after the native or replacement valve is excised, figure-of-8 sutures of nonabsorbable material are placed through the fibrous heads of each papillary muscle. The sutures from the anterior heads of the papillary muscles are then passed through the mitral annulus at the respective commissures. The sutures from the posterior heads are placed posterior to each commissure. The sutures are tied to fix the proper distance between the papillary muscles and the annulus. After the prosthesis is inserted in the usual manner, the ends of these tethering sutures are also passed through the sewing ring of the replacement prosthesis to transfer the stress to the prosthesis.

This technique thus simulates preservation of the "chordae." The benefits of preventing "untethering" of the left ventricle [2] are thus achieved without complex, time-consuming maneuvers, and without the risk of left ventricular outflow obstruction.

Direct Mechanical Ventricular Actuation

To the Editor:

I was happy to read the recent article by Lowe and associates [1] entitled "First successful bridge to cardiac transplantation using direct mechanical ventricular actuation." This concept was developed by my colleagues and I in the 1960s for resuscitating an arrested heart and published in the *Indian Journal of Surgery* [2, 3]. We developed a cardiac assisting device for pulsating the heart during cardiac arrest and found this principle very effective in animal subjects. I am very happy to note that the same principle has now been used as a bridge to cardiac transplantation.

My heartiest congratulations to the authors of this article, who have found it effective for heart transplant patients waiting for a suitable donor heart.

Reply

To the Editor:

We appreciate Dr Khanna's comments concerning our article. Doctor Khanna's cited publications demonstrate that he experimented with a device similar to direct mechanical ventricular actuation (DMVA). We feel compelled to point out, however, that George L. Anstadt, VMD, first described and successfully developed this technology in the 1960s, years before Dr Khanna and associates published their two manuscripts.

In 1945, George L. Anstadt witnessed his father's sudden death due to a massive heart attack. Later that year, his attention was drawn to a picture of the iron lung on the cover of *Life* magazine, and he contemplated how he could apply this concept to the arrested heart. It is interesting that to this day he likens his heart cup to an "iron lung" for the heart. The initial DMVA experiments took place at the USAF School of Aerospace Medicine, San Antonio, Texas, from 1960 to 1962. During this time, Dr Anstadt bonded surgical gloves inside modified aluminum funnels to make a prototype of the concept. Explanted canine hearts were aspirated into the crude devices by means of a vacuum delivered through the funnel's spout. The funnel-housed glove was then pneumatically inflated and deflated to actuate the

asystolic heart. These experiments represent the earliest bench testing of DMVA.

Doctor Anstadt subsequently wrote and successfully defended his thesis, "A study in the development of an effective method of direct mechanical ventricular assistance" at the University of Pennsylvania (Sep 1963-Aug 1965). He gave the first public presentation of DMVA at the 38th Scientific Sessions of the American Heart Association [1]. More than 50 subsequent publications have reported successful utilization of his method in both laboratory and clinical settings [2].

Although various mechanical cardiac compression devices have been described by other investigators [3-7], no method other than DMVA uses a uniquely nontraumatic means of application (a vacuum) and effectively participates in the diastolic phase of the cardiac cycle.

Ongoing investigations at Duke University Medical Center are aimed at testing DMVA for long-term circulatory support. Recent clinical applications have been restricted to well-selected patients in either refractory cardiac arrest or failure who meet selection criteria for cardiac transplantation. Even if the cardiac failure is irreversible, an eventual therapeutic end-point is still possible. Although bridging to transplantation may be viewed as a new application for DMVA, the inventor, George L. Anstadt, VMD, realizes it is simply a prolonged exercise in resuscitative circulatory support.

We appreciate Dr Khanna's supportive letter regarding our recent success, but wish to emphasize that Dr Anstadt deserves recognition for first describing DMVA and subsequently developing it to its current state. Doctor Anstadt's dedication of personal time and effort to this technology has persisted for more than 30 years. We hope that ongoing efforts at Duke University will demonstrate the broad clinical potential for this very unique and promising technology, which provides non-blood contacting, biventricular, total circulatory support.

Intraaortic Balloon Position

To the Editor:

I read with particular interest the article published in the April issue of *The Annals* [1] entitled "Effects of Intrathoracic balloon

position on renal artery blood flow." My interest is due to the fact that in my 61-patient experience with right gastroepiploic artery (RGEA) for myocardial revascularization, I had 2 patients in whom I had to insert an intraaortic balloon pump. In those patients the RGEA was used to bypass the posterior descending branch of the right coronary artery, and a postoperative inferior myocardial infarction occurred, as documented by electrocardiogram and creatine kinase-MB level. Angiography performed 1.5 months after operation showed a patent RGEA graft.

Do you think, as I do, that the intraaortic balloon pump influences the flow in the RGEA? Although the explanation could be based on a spasm due to the characteristics of a muscular artery such as the RGEA, I would like very much to hear your opinion on that subject.

Ionescu-Shiley Standard-Profile and Low-Profile Valves To the Editor:

The recent companion articles [1, 2] on failed Ionescu-Shiley standard-profile and low-profile valves contain valuable information about tissue failure mechanisms and valve design. However, there is a problem with the reasoning used to justify their conclusion [2] that: "... low-profile valves ... fail after a shorter time in situ than their standard-profile counterparts, at a mean of 45.1 months versus 78.0 in the aortic position ($p < 0.01$) and at 52.2 months versus 73.8 in the mitral position ($p < 0.05$)."

The problem is that the standard-profile valves were implanted earlier and followed up for a longer time, on average, than the low-profile valves. The mean time to failure in an ongoing series will depend on the amount of time the series has been followed up and will, in general, be larger in longer series that are otherwise similar.

In Table 1, the mean failure times are weighted combinations of those given above for both positions and converted to years. For both valve models, the mean failure time is about 75% of the midpoint of the range of potential follow-up years. Thus, this very crude method of adjusting for the differences in follow-up times completely accounts for the apparent difference in mean failure times. A proper way to compare failure times is to use the

Table 1. Relationship of Failure Times to Follow-up Years

Variable	Standard-Profile	Low-Profile
Mean failure times (y)	6.4	4.0
Implant dates	4/77-6/86	12/81-8/88
Follow-up date	7/1/90	7/1/90
Potential follow-up years	4.1-13.3	1.9-8.6
Midpoint of follow-up years	8.7	5.3

actuarial method, as their group did in their previous excellent review of these series [3].

Reply

To the Editor:

We would like to thank Dr Grunkemeier for his thoughtful comments on our article [1]. In our view, there is substantial overlap in the implanted times of the standard-profile and low-profile valves from the series. As noted by Dr Grunkemeier, the appropriate manner in which to analyze failure time data is using actuarial methods. Unfortunately, not all of the necessary data were available to us; therefore, we used a crude analysis, independent Student's *t* tests, to address the important question "were there differences in in-situ times between standard-profile and low-profile valves?" As mentioned in our article, the more extensive clinical analysis from this series has previously been published [2].

Thoracoscopic Excision of Bronchogenic Cysts

To the Editor:

We found the current review on asymptomatic bronchogenic cysts by Bolton and Shahian [1] to be both an interesting and

useful treatise. However, in our minds, the management comments of the review are probably already outdated. We believe that thoracoscopic removal of all types of mediastinal cysts can be accomplished in most patients without thoracotomy, using the same surgical caveats that one would use in an open technique. Lewis and associates [2] reported a video-assisted technique that also accomplishes the same results. Thoracoscopic excision of mediastinal cysts is rapidly becoming accepted as a standard surgical treatment.

Because a less invasive method to reliably diagnose and definitively treat bronchogenic cysts now exists, the threshold for recommending treatment of bronchogenic cysts should probably also change. We certainly believe that the morbidity of thoracoscopy better matches the morbidity of the disease process than does thoracotomy. Because the review did not address the expanded role of thoracoscopy in the management of bronchogenic cysts, do Bolton and Shahian believe their recommendations should change? Specifically, in view of a less invasive approach, when do Bolton and Shahian believe that thoracoscopic removal of a cyst is preferable to long-term observation?

Reply

To the Editor:

We agree with Drs Acuff and associates that imaged thoracoscopic surgery may be very useful for the removal of some bronchogenic cysts, and we mention this specifically in our article. This technique may be employed for the diagnosis and treatment of enlarging, symptomatic, or atypical cystic lesions. However, the fact that a less invasive procedure exists does not necessarily constitute an indication for operation. There is still a role for observation of small, classic asymptomatic bronchogenic cysts.

Circulatory Support 1991

THE SECOND
INTERNATIONAL
CONFERENCE
ON CIRCULATORY
SUPPORT DEVICES
FOR SEVERE
CARDIAC FAILURE

November 15-17, 1991 • San Francisco Marriott • San Francisco, California

Circulatory Support 1991

On November 16 and 17, 1991, in San Francisco, a special session entitled "Circulatory Support 1991" sponsored by The Society of Thoracic Surgeons featured presentations summarizing current practices with circulatory support devices of all types. International experts from clinical, engineering, industrial, and regulatory disciplines met and exchanged experiences and opinions. Formats for presentation included formal presentations, panel discussions, and focused "break-out" groups. Most of the information from that meeting is presented in this supplement to *The Annals of Thoracic Surgery*. It consists of scientific papers, "state of the art" summaries, transcribed and edited panel discussions, and position papers of industry, clinicians, the Food and Drug Administration, and the FDA Devices Panel.

This meeting was planned as a sequel to Circulatory

Support 1988 by the STS Ad Hoc Committee on Circulatory Support Devices, including D. Glenn Pennington (Chairman), Bartley P. Griffith, Charles-Julien Hahn, J. Donald Hill, Larry R. Kaiser, George J. Magovern, Walter E. Pae, Peer M. Portner, Glenn Rahmoeller, and myself. I would like to thank the committee members, the other participants, and the discussants for their efforts to make the meeting and the record of the meeting a dynamic exchange of ideas and a point of reference for the future. I would also like to thank The Society of Thoracic Surgeons for their leadership in supporting the meeting and the supplement, and the editorial office of *The Annals* for their help.

Guest Editor

Program

■ Saturday, November 16, 1991

8:00–8:15 **Welcome and Opening Remarks**
D. Glenn Pennington, Chairman, Ad Hoc Committee on Circulatory Support and Thoracic Transplantation of The Society of Thoracic Surgeons

Problem Case Oriented Panels

8:15–8:55 **Panel I: Patient Selection***
Moderator: D. Glenn Pennington, St. Louis, MO
Panelists: David J. Farrar, San Francisco, CA
Daniel Loisançe, Paris, France
Walter E. Pae, Jr, Hershey, PA
Robert W. Emery, Minneapolis, MN

8:55–9:15 **Registry Report***
Walter E. Pae, Jr, Hershey, PA

9:15–10:05 **Video Session I**
Discussion Leader: W. Gerald Rainer, Denver, CO

10:05–10:50 **Break**
Visit Exhibits/Posters

10:50–11:40 **Video Session II**
Discussion Leader: Wilbert J. Keon, Ottawa, Canada

11:40–12:30 **Video Session III**
Discussion Leader: Ernst Wolner, Vienna, Austria

12:30–1:30 **Luncheon**

1:40–2:40 **Three Breakout "How To" Panels—Session I**

1. Nonpulsatile Circulatory Support: Techniques of Insertion*
Moderator: George J. Magovern, Jr, Pittsburgh, PA
Panelists: Richard K. Wampler, Rancho Cordova, CA
Lyle D. Joyce, Minneapolis, MN
Thomas H. Wareing, St. Louis, MO

2. External Pulsatile Circulatory Support
Moderator: J. Donald Hill, San Francisco, CA

Panelists: Yukiyasu Sezai, Tokyo, Japan
Roland Hetzer, Berlin, Germany
Robert A. Guyton, Atlanta, GA

3. Internal Pulsatile Circulatory Support*
Moderator: Peer M. Portner, Oakland, CA

Panelists: William A. Baumgartner, Baltimore, MD
Christian Cabrol, Paris, France
O. H. Frazier, Houston, TX

1:40–2:40

Cardiac Nursing Breakout Session
Nursing Care of the Patient on Mechanical Circulatory Support*
Moderator: Julie A. Shinn, Stanford, CA

1. Transfer of VAD Patients to Non-Critical Care Areas
Nancy Abou-Awadi, Houston, TX
2. Nutritional Support and Activity Guidelines
S. Jill Ley, San Francisco, CA
3. Infection Control Measures
Jane Reedy, St. Louis, MO
4. Psychosocial Aspects of Care
W. Donald Rountree, Louisville, KY

2:45–3:45

Three Breakout "How To" Panels—Session II

1. Nonpulsatile Circulatory Support
Moderator: George Paul Noon, Houston, TX
Panelists: Jack J. Curtis, Columbia, MO
Charles Henry Moore III, San Antonio, TX
Michael S. Sweeney, Houston, TX
2. External Pulsatile Circulatory Support*
Moderator: Charles-Julien Hahn, Arzier, Switzerland
Panelists: William L. Holman, Birmingham, AL

* This presentation is published in this special section.

- Jack G. Copeland III, Tucson, AZ
Gerard Champsaur, Lyon, France
3. Internal Pulsatile Circulatory Support
Moderator: Philip E. Oyer, Stanford, CA
Panelists: Robert L. Kormos, Pittsburgh, PA
Terence Lewis, London, England
Roque Pifarre, Maywood, IL
- 3:45–4:30 **Break**
Visit Exhibits/Posters
- 4:40–5:10 **Panel II: Anticoagulation***
Moderator: Jack G. Copeland III, Tucson, AZ
Panelists: O. H. Frazier, Houston, TX
Lawrence R. McBride, St. Louis, MO
Marko Turina, Zurich, Switzerland
Christian Cabrol, Paris, France
- 5:10–5:50 **Panel III: Infections—Prophylaxis and Treatment***
Moderator: J. Donald Hill, San Francisco, CA
Panelists: Bartley P. Griffith, Pittsburgh, PA
Marco Meli, Sion, Switzerland
Paul Didisheim, Bethesda, MD
- 5:50–6:30 **Panel IV: Management of Secondary Organ Dysfunction***
Moderator: William S. Pierce, Hershey, PA
Panelists: James J. Hershon, San Francisco, CA
Robert L. Kormos, Pittsburgh, PA
Walter P. Dembitsky, San Diego, CA
George Paul Noon, Houston, TX
- 6:45–7:45 **Welcome Reception**

■ Sunday, November 17, 1991

- 6:40–7:40 **Special Breakfast Panel V: Long-Term Biventricular Assist***
Moderator: Charles-Julien Hahn, Arzier, Switzerland
Panelists: William S. Pierce, Hershey, PA
Don B. Olsen, Salt Lake City, UT
Kenneth Butler, Rancho Cordova, CA
Robert T. V. Kung, Danvers, MA
- 7:45–9:20 **State of the Art I**
Moderator: Frank C. Spencer, New York, NY

1. Emergency Resuscitation Using Portable Extracorporeal Membrane Oxygenation*
Walter P. Dembitsky, San Diego, CA
2. Circulatory Support With Heparinless CPB
Per Olsson, Stockholm, Sweden
3. Hemopump: Clinical Results and Applications
Richard K. Wampler, Rancho Cordova, CA
4. The Biopump and Postoperative Circulatory Support*
George J. Magovern, Jr, Pittsburgh, PA
5. Clinical Experience With Ventricular Assist Systems in Japan*
Hisateru Takano, Osaka, Japan

- 9:20–10:05 **Break**
Visit Exhibits/Posters

- 10:05–11:40 **State of the Art II**
Moderator: Michael E. DeBakey, Houston, TX
6. Optimizing Hemodynamics and Assessing Myocardial Recovery
George Paul Noon, Houston, TX
 7. Circulatory Support With Shock due to Acute Myocardial Infarction*
Ernst Wolner, Vienna, Austria
 8. Circulatory Support in Infants and Children*
D. Glenn Pennington, St. Louis, MO
 9. World Experience With Skeletal Muscle Cardiac Assist
James A. Magovern, Pittsburgh, PA
 10. Current Expectations in Dynamic Cardiomyoplasty*
Adib D. Jatene, Sao Paulo, Brazil

- 11:40–12:00 **Break**
Visit Exhibits/Posters

- 12:00–1:35 **State of the Art III**
Moderator: Norman E. Shumway, Stanford, CA
11. Right Heart Management During LVAD Support
Bartley P. Griffith, Pittsburgh, PA
 12. Univentricular and Biventricular Thoratec VAD Support as a Bridge to Transplantation*
J. Donald Hill, San Francisco, CA

-
13. Bridge to Transplantation With the Symbion J7 TAH
Christian Cabrol, Paris, France
 14. Chronic Left Ventricular Support With a Vented Electric Assist Device*
O. H. Frazier, Houston, TX
 15. Chronic Support With the Novacor LVAS
Peer M. Portner, Oakland, CA

1:35 **Close of Main Session**

2:30-4:00

FDA Regulatory Issues Session

How Much Do We Need to Know Before Approving a Ventricular Assist Device?*

Moderator: J. Donald Hill, San Francisco, CA

Panelists: Bette Lemperle, FDA Reviewer

Mark Levinson, FDA Advisory Committee Member

Victor L. Poirier, Industry Perspective (Thermo Cardiosystems, Inc)

Bartley P. Griffith, Clinical Perspective

4:00-5:00

Question and Answer Session

* This presentation is published in this special section.

Panel I

Patient Selection

Moderator: D. Glenn Pennington, MD

Panelists: David J. Farrar, PhD, Daniel Loisance, MD, Walter E. Pae, Jr, MD, and Robert W. Emery, MD

MODERATOR PENNINGTON: Our first session is entitled "Patient Selection." Many of us believe this is the key to the appropriate use of these devices. There is much to learn about patient selection even today after several years of working with these devices. It has been estimated that in the United States there are 250,000 cardiac surgical procedures performed per year. Somewhere between 1% and 7% of those patients require an intraaortic balloon pump. Of those receiving an intraaortic balloon after a cardiac operation, about 65% survive. However, fewer than 1% of patients receive a ventricular assist device (VAD) [1]. Therefore, it appears that we are under-using our capability with these systems. This suggests to me that postcardiotomy is one of the areas that needs reevaluation of our use of these systems.

How does the use of assist devices compare with conventional treatment in our cardiac transplant population? We have struggled with the notion that patients requiring circulatory support would be less than optimal candidates for transplantation. But when we reviewed our own series and looked only at status 1 patients, that is, patients who were supported with mechanical devices such as a VAD as opposed to those supported with drugs and a balloon pump, we found that the VAD patients had lower mortality rates both initially and in the follow-up. So it appears that some of the patients we are supporting with "conventional" measures, including intraaortic balloon pumping, might be better served by ventricular assist device support [2]. Daniel Loisance will take me to task about that later on in our discussion.

I would like to introduce our first panelist, Walter Pae, who will cover the question of how to select patients for postcardiotomy support.

DR PAE: Thank you, Dr Pennington. Doctor Pennington has asked me to briefly deal with patient selection in regard to postcardiotomy cardiogenic shock and aggressive circulatory support. I might preface this by saying that perhaps in this particular area, despite a very, very large clinical experience, more is known regarding who is at risk of not surviving than the converse. Despite the recent advances in myocardial preservation and the techniques in cardiac surgery in general, we all recognize that we are operating on high-risk patients. These risks tend to offset the improvements and lead to a reported steady incidence of postcardiotomy cardiogenic shock, which, as

mentioned, occurs in somewhere between 1% and 7% of all patients who undergo cardiac surgical procedures.

Now I believe a consensus exists among most cardiac surgeons that after a cardiac operation a cardiac index of less than 1.7 to $2.0 \text{ L} \cdot \text{min}^{-1} \cdot \text{m}^{-2}$ coupled with elevated systemic vascular resistance and pulmonary capillary wedge pressure along with arterial hypotension carries a very high probability of cardiac death. However, despite the efficacy of inotropic drugs and the intraaortic balloon to "reverse this low output syndrome," or improve the hemodynamic parameters in 75% to 85% of patients, survival is still widely variable and reported in the literature to be in the 30% to 65% range. I believe the issue in terms of patient selection, given the relative safety and efficacy of the current devices, is at what point aggressive circulatory support should be instituted. How much drug therapy in addition to the intraaortic balloon should be "tolerated" by the surgeon to the detriment of the myocardium and other organ systems to achieve "suitable hemodynamics," only to have an unsuitable patient outcome? Unfortunately, at this time, there is a large gap in our knowledge, and appropriate clinical studies are really needed to answer these pivotal questions. It is certainly reasonable to hypothesize that the outcome in these critically ill patients will be improved if circulatory support is instituted earlier but not inappropriately. Hopefully in the discussion some of these issues can be addressed.

In the next session, encompassing the registry report, I will attempt to detail a number of issues regarding patient selection in relation to survival in both postcardiotomy cardiogenic shock and the bridge to transplantation application. However, I would like to emphasize certain points here as well. In this relatively large database there are certain themes that are recurrent. First, the outcome appears to be unrelated to the original operative procedure. Although the rates of weaning from devices after cardiotomy does not differ statistically, there is a decreasing probability of hospital discharge in those patients more than 70 years of age. This would indicate that although myocardial recovery occurs, the physiological reserve is quite limited in the elderly population, leading to only an overall 13% salvage rate in this particular age group [3]. Now, severe biventricular failure and perioperative infarction alone or in combination are very powerful predictors of ultimate survival [4-6]. Some investigators, including our illustrious moderator, have stated that unless a patient is a transplant candidate they would not institute postcardiotomy ventricular assist under the

circumstances of known perioperative infarction and severe biventricular failure. Unfortunately, although biventricular failure is easy to diagnose at operation, perioperative myocardial infarction may be considerably more difficult to establish intraoperatively. Finally, although not precisely patient related, bleeding remains a powerful negative predictor of survival and seems to be more highly associated with vortex pump systems. Although prolonged cardiopulmonary bypass has multiple organ effects, certainly increased bleeding is a well-recognized complication, and poor results are seen with longer bypass times of 4 to 6 hours. Therefore the ideal patient, although difficult to find, is less than 70 years old, has had a technically satisfactory operation, does not have any preexisting organ dysfunction, and has had a short cardiopulmonary bypass time. Univentricular failure predominates and perioperative infarction is unlikely. I think I will stop here to keep within the time constraints and to allow for some discussion.

MODERATOR PENNINGTON: We will have our discussion after all of the panelists have presented. Next David Farrar will give us some thoughts about choosing the bridge to transplantation patient.

DR FARRAR: Thank you, Dr Pennington. I would like to speak to you briefly as the study monitor for the Thoratec VAD. It is very clear to me after reviewing all the patients in our study and talking to all the investigators that we might even list the three most important factors as patient selection, patient selection, and patient selection [7]. However, let us not forget early VAD implantation, to which Dr Pae alluded, which may even be more important. One of the problems we have, of course, in evaluating the data is how to quantitate factors of patient selection so these can be submitted to the Food and Drug Administration and examined for reasonable variables. This is, indeed, a very difficult thing to do, particularly on an individual patient basis. It is pretty easy to say that the ideal candidate for bridging to cardiac transplantation is somebody who has single organ disease. The patient we would like to bridge has irreversible heart failure before any irreversible failure of end-organ function and no contraindications to heart transplantation. The difficulty appears to be in determining when irreversible failure of end-organ function has occurred that would contraindicate use of a VAD.

I would like to discuss briefly a few things we have done looking at preoperative variables in our database, which consists of 151 patients who were implanted with a Thoratec VAD for bridging to transplantation: 118 male and 33 female patients. The average age is 42 years, with a range of 11 to 64 years. There is a wide range in weight, from the smallest patient of 30 kg to the largest of 123 kg. Sixty-three of these patients had coronary artery disease, 73 had nonischemic cardiomyopathies, 8 were posttransplantation, and 7 had other cardiac disease. We looked at some of the preoperative variables in this patient population and tried to retrospectively determine in the patients who died the effect of preoperative variables. Thirty-five

percent of the patients died before transplantation—the largest mortality. Only 16% died after transplantation, so there is an 84% posttransplantation survival. There were 82 survivors after transplantation, 54% of the total in whom a VAD was implanted.

Are there any preoperative variables that can predict why patients died before transplantation? If we look at 15 potential risk factors in our database—age, sex, body surface area, diagnosis, previous operation, intraaortic balloon pump, mechanical ventilation, cardiac arrest, whether the implant was emergent or not, whether the patient came from the postcardiotomy support group as opposed to primary bridge, hemodynamics, cardiac index, pulmonary capillary wedge pressure, other system disease, blood urea nitrogen (BUN), creatinine, and bilirubin—four factors were significant: age, sex, previous operation, and BUN. Doctor Pae just alluded to the effects of age. We found an interaction between age and sex; male and female patients old and young have to be separated for these to become significant factors. Previous operation was extremely significant, as was BUN. In patients with previous cardiac operations, there was only 33% survival to transplantation, whereas those who did not have previous cardiac operations had a 67% survival to transplantation. If we divide patients above and below the median age of 42 years, there is improved survival in the younger group. Males have 77% survival and females 56% survival. But among older patients, males had a 60% survival and females had only a 30% survival. Also, there is a greater difference between older females and younger males. These are very significant risk factors. I would like to point out that I did not realize the importance of BUN until about a week or two ago when preoperative laboratory values were analyzed and we found elevated BUN to be a significant risk factor for survival. We stratified the data based on preoperative BUN and survival to transplantation. Patients with a BUN of less than 20 mg/dL preoperatively had a 75% survival; 20 to 30 mg/dL, 69%; 30 to 40 mg/dL, 62%; 40 to 70 mg/dL, 50%; and greater than 70 mg/dL, 25%. Kidney function in and of itself is not predictive in that if we look at creatinine level we do not see the same slope. If preoperative creatinine level is less than 1.5 mg/dL, survival is 66%; at 1.5 to 1.9 mg/dL, 64%, the same percent survival all the way up to a creatinine level of 3 mg/dL. At a creatinine level greater than 3 mg/dL, the survival drops off quite sharply to 25%. In summary, there are some preoperative values that do help predict success for the bridge to transplantation procedure.

MODERATOR PENNINGTON: Some of us have had the terrible problem of trying to deal with a patient after transplantation who simply did not do well and required circulatory support. Our own results have been so bad that retrospectively we would have excluded most of those patients from support. Robert Emery has some new lessons for us, and we will ask him to give those now.

DR EMERY: Thank you, Dr Pennington. The patients who have undergone transplantation, if we adhere to our

usual criteria for selecting transplant candidates, should be ideal candidates to support with mechanical devices should the organ fail, and I think the data that Drs Farrar and Pae have given support this. There are a number of reasons why a donor organ can fail when you take a supposedly healthy organ, remove it for several hours, and reimplant it. High pulmonary vascular resistance is a recipient-mediated factor, as are others, including a previous cardiac operation with technical difficulty or the removal of a bridge device with adhesions that make the implantation procedure difficult, preoperative cardiac medications such as amiodarone, or multiorgan system failure in patients before transplantation. Procurement or donor-mediated factors for failure of the donor heart include premortem myocardial injury, preservation injury, unknown sepsis in the donor, prolonged ischemic time, the use of a "nontraditional" donor, and deleterious effects of a multiple organ harvest. The latter I think is very important, having noticed substantial difference in cardiac recovery from the days when we used to just remove the heart and the kidneys to the present time when organ harvest is a 4- or 5-hour operation for the general surgeons to remove the liver, kidneys, and pancreas. The increased magnitude of the procedure has a significant effect on cardiac function after removal from the donor. Furthermore, we are utilizing older donors and those with circulatory diseases such as hypertension that we do not exclude now because of our donor organ shortage. A donor organ or a donor-recipient size mismatch or acute rejection may also complicate organ recovery. Of course, the ubiquitous acts of God that we all have to deal with at times occur.

Our experience with donor hearts that have failed consisted of 11 patients aged 19 to 63 years with a donor age of 23 to 47 years [8]. The ischemic time was 76 to 255 minutes. The devices used included the Symbion J-7-70 device (1), right VAD (3), left VAD (2), biventricular assist devices (4), and the intraaortic balloon pump (1). I should note all the patients who had VADs put in had balloon pumps as well, and 2 patients had multiple devices. In these 11 patients there were three deaths. The first death occurred in a patient who had cardiac arrest the day after the right VAD was removed, and I suspect there was ongoing right heart failure, but we did not have the use of a transesophageal echocardiogram then that we would now use to inspect the cardiac function before removal. The last patient was weaned from the device but had a stroke during the transplant procedure. The third death occurred in the operating room because we were not able to support the patient effectively. It is of note, however, that all but one of those hearts recovered.

The patients who survived are currently all long-term survivors and are in functional class I. In the patient who we were unable to support, postmortem examination revealed an anatomic abnormality of a super dominant right coronary artery, a diminutive left coronary artery, and an ostial lesion of the right coronary artery in this 36-year-old man. We believe he had a huge biventricular infarction at the time of organ retrieval.

We can, therefore, support such patients after trans-

plantation and can support them quite well. Also, we can expect recovery of the heart with appropriate application of support, which I believe should be early. We have tried to learn some things from this experience, and though I agree with Dr Farrar's patient selection hypothesis, in this group the patients are generally well selected and probably stress should be placed on early utilization, early utilization, early utilization. We limit the use of inotropic medications after transplantation to standard isoproterenol and low-dose dopamine. Occasionally we will add epinephrine, but if we have to go to more than 2 $\mu\text{g}/\text{min}$, depending on patient size, we will quickly look to a balloon pump and possibly get things in place for a VAD. It is important to eliminate distention injury in the transplanted heart. The acutely denervated heart loses a number of protective intrinsic reflexes, which can lead to more extensive damage in these hearts if distention occurs. We initiate right support earlier than left support because the danger in the right ventricle seems to occur early and the recovery of the right ventricle seems to take longer, as evidenced in the support of patients who required a right VAD for 7, 10, and 14 days as opposed to patients with left ventricular support, who recovered within 2 to 3 or 4 days. We have only had to use univentricular support in most patients; however, 2 patients had biventricular support, both of whom had serious ischemic injuries of the heart due to very difficult implantations after Jarvik removal.

Complete drainage of the affected ventricle is important. We only use as much inotropic support as is required to affect the working ventricle after VAD implantation. The VAD lines exit through separate incisions. The outflow line is placed in the superior pulmonary vein on the right using a 26F angled catheter that allows 5 L/min of flow, and the inflow cannula is placed in the ascending aorta under the sternum so that a tangential trajectory is achieved, assisting in obtaining hemostasis. The sternal incision is used in standard fashion, which allows these patients to wake up and be extubated in the postoperative period. We follow up the return of ventricular function by loading the ventricle while observing the transesophageal echocardiogram, a useful tool in the timing of weaning and removal of a device, and we do not use heparin except in the case of a total artificial heart or in our centrifugal VADs when the flow is less than 2 L/min. At 1 to 2 L/min flow the activated coagulation time is kept greater than 180 seconds, and at less than 1 L, greater than 300 seconds.

In summary, the patients are selected after transplantation. Most of them are good candidates for support, and we believe that if support is initiated early enough with the proper devices going from the simplest to the more complicated, good long-term survival can be effected.

MODERATOR PENNINGTON: Well, we all struggle with the question of whether or not we should proceed with our pharmacological agents to try to support patients in either category of postcardiotomy or bridging to transplantation, or whether we should go ahead and use mechanical devices. There are some differences of opin-

ion, and Daniel Loisanse has thought about this a great deal, has written about it and we are delighted to have him give us his opinions.

DR LOISANCE: Thank you, Dr Pennington. It is a real pleasure to fly from Paris to the California vineyards and discuss with you the issue of patient selection and what we try to do in Paris. What we try to do is to use a very flexible strategy, providing patient support with enoximone, which at the same time would permit us to avoid the rising cost of health care [9]. In this strategy, we initially use medical therapy; if the patient is responsive, he or she is bridged pharmacologically to the transplantation. If the patient is not responsive to enoximone, mechanical bridging is immediately undertaken. Should a patient's condition deteriorate on the pharmacological bridge, the patient will immediately be switched to the mechanical bridge.

Our experience is now based on 52 patients and all have been referred for transplantation or immediate mechanical bridge. All were unresponsive to maximal therapy including in a few patients intraaortic balloon pumping. All these patients had good indications for transplantation, and 4 were in deteriorating condition while on the waiting list. Most of our cases were acute, arising from a very recent history of ischemic cardiomyopathy or idiopathic cardiomyopathy. Fifteen of these patients had recent acute myocardial infarction. Only 8 patients were unresponsive to enoximone pharmacological support, and they underwent immediate transplantation. In 44 patients, the improvement was such that it was possible to gain time to restart the evaluation process and to either reconfirm the indication for transplantation or even find some contraindication to this transplantation. Twenty-six patients of the whole group of 52 were reconfirmed as good candidates. At 1 month 23 patients were living after either a mechanical bridge or a pharmacological bridge. Eight patients were still waiting for transplantation, most in stable condition at home. Eight patients had a contraindication to transplantation. They are living at home, in stable condition. At 1-year follow-up 20 patients were still living and 14 have undergone transplantation; 4 with a contraindication are still living and 2, who were sent to us for cardiac replacement, have been removed from the transplant list because of a recovery of myocardial function.

The most important reason for this strategy is cost savings. Forty-three devices costing approximately \$2.3 million US dollars were not used. We also better utilize organ grafts, which are used for patients with true indications for transplantation. In other words, we are trying to combine the patient's interest, which is obviously to stay alive, and the social concern, which is to avoid excessive rising costs in health care. There is obviously a black side to the picture. The concerns about this strategy are related to both the nonresponsive patients and the responsive patients. In the nonresponsive patients, what we may see is some form of super-maximal vasodilator action leading to prolonged organ dysfunction and to a delayed decision for implantation. This obviously in-

creases the risk to the patient for a device, the loss of vascular tone leading to the risk of irreversible failure of other organ systems and, finally, to a reduction in the transplantability of the patient on a device. The second concern is about the patients who are responsive to enoximone. They are living because of a major hemodynamic improvement, but they are at risk of sudden death, which may occur while they are still in the intensive care unit. We had 4 such patient deaths. Patients also have a sudden death risk after hospital discharge when they are in otherwise stable condition at home waiting on the list. We have lost 2 such patients. In other words, there is a 23% rate of sudden death among the population of patients who are ideal candidates for transplantation and who were in otherwise stable condition. This is quite unacceptable if we recall that this therapy was successful to resuscitate the patient in terminal condition. A second concern in this group of patients who are dramatically improved from a hemodynamic point of view is the incompleteness of the recovery process. When they are in the intensive care unit they are bedridden, and when they are at home they do not exercise as they should. So we do not achieve an ideal quality of life. This leads to the conclusion that we should not ask too much, but we should be reminded that this strategy is definitely a major help in the selection process of our patients.

MODERATOR PENNINGTON: Thank you very much, Dr Loisanse. I am sure many of you have comments or questions, and we want to entertain those. While you are thinking and getting ready to come to the microphone I will ask a couple of questions. Doctor Loisanse, we do not have enoximone but we do have dopamine, dobutamine, isoproterenol, and epinephrine, among other drugs. Do your patients receive any conventional drugs before enoximone or do they just go right to enoximone?

DR LOISANCE: All of these patients are first treated with dobutamine, dopamine, norepinephrine, all these cocktails. And if this does not work we add enoximone to the previous medical therapy. So, it is not a substitution but an addition.

MODERATOR PENNINGTON: I think we stated in our own experience that those patients with ventricular assist devices before transplantation did much better than those supported with drugs or intraaortic balloon pumps before transplantation [2]. Was there a difference in your two groups in terms of their survival or outcome after transplantation?

DR LOISANCE: No, the risk of transplantation is about the same.

MODERATOR PENNINGTON: I see, so it does not make much difference whether they got there by way of a mechanical device or drugs. Is that right?

DR LOISANCE: Correct.

MODERATOR PENNINGTON: Are there questions from the audience?

MR BRUCE SHOOK (Danvers, MA): I have a question for David Farrar. You presented some interesting data that would appear to be predictors of success, BUN for example, and I wondered if you could tell us whether you identified anything else that was statistically meaningful in the course of your analysis.

DR FARRAR: Actually those parameters that I presented were the ones that were significant. All had *p* values less than 0.05. Blood urea nitrogen was highly significant; creatinine was not. Previous operation and the interaction between age and sex were important. Older females did much worse than the younger males.

MODERATOR PENNINGTON: I think what we are being asked to do by the FDA, at least in this country, is to define precisely which patients we are evaluating in terms of those requiring mechanical support. And I think the data that Dr Loisanse presented and the data we are trying to generate at St. Louis University attempt to do that. For example, we have established a set of criteria based on drug dosages: 10 μ g of dobutamine, 10 μ g of dopamine, various limits of epinephrine and isoproterenol. Once we get beyond those limits, then the patient's chance is better to have a mechanical device than it is to continue on pharmacological support. And as much as we dislike that sort of "cookbook" criteria, we are being asked to develop such criteria to defend our practices.

DR GEORGE J. MAGOVERN, JR (Pittsburgh, PA): I wanted to ask Dr Emery what his experience has been with treating patients who have acute right heart failure after transplantation with right ventricular assist, and how successful that program has been in having those patients reverse their failure.

DR EMERY: You mean right ventricular assist alone?

DR MAGOVERN: Right or biventricular assist.

DR EMERY: I think that we have four biventricular assist devices and three right VADs alone. We do try to use only univentricular assistance, but, as I mentioned, 2 of the patients with biventricular assist devices had global ischemic injury with difficult implantations after bridging. The patients with right VADs were all able to be weaned. The first patient died, I think because we did not wait long enough and support him long enough for ventricular recovery. He went on the device because there was prolonged organ ischemic time and particularly high pulmonary vascular resistance in the range of 6 Wood units at the time of transplantation. We have been able to get all the right ventricular assist patients off the device, but there have only been three used. We do try to put the balloon pump in very early. And that has impressed me as helping people who might have right ventricular dysfunction by decreasing the afterload of the right heart by

unloading the left. I really think that early intervention on the right side is particularly important because when the right ventricle gets stretched, particularly if it has to recover against a relatively high afterload after transplantation, recovery takes a long time.

DR TIMOTHY B. ICENOGLE (Spokane, WA): It is not infrequent that pleas or cries for help come to centers that have such devices. Given the hypothetical situation of a call from a center across town where there is a 40-year-old person who has had a catheterization laboratory crash and operation and now is on biventricular assist but awake and making urine, would any of the panelists consider that patient as a candidate for a pulsatile assist device?

MODERATOR PENNINGTON: Well let me just answer that in our own center we have had several cross-city transfers. Actually we have received patients on centrifugal pumps. And we just believe that is a reasonable thing to do because it is not possible that every cardiac center become a transplant center. Therefore, that makes it incumbent upon the transplant centers to try to take care of this population of patients. Unfortunately I have to report that none of our transfer patients have made it to transplantation. Do you accept patients from outside, Dr Emery?

DR EMERY: We have tried not to.

MODERATOR PENNINGTON: Doctor Pae?

DR PAE: We do, but we have basically had the same experience as you. We have been unsuccessful.

MODERATOR PENNINGTON: Doctor Loisanse?

DR LOISANCE: We are a referral center, so we cannot avoid taking care of these patients. We have to take them.

MODERATOR PENNINGTON: Even if they are on a balloon pump or some other type of device?

DR LOISANCE: Yes, that is exactly the kind of patient that we are referred the most.

MODERATOR PENNINGTON: And . . .

DR LOISANCE: We do but the results are quite bad also.

DR ERIC A. ROSE (New York, NY): I would like to ask Dr Loisanse about the patients who are switched from intravenous to oral enoximone. In those patients do you use angiotensin-converting enzyme inhibitors as well or preferentially? Enoximone in this country in the class IV heart failure trials has actually shown increased patient mortality. Arnold Katz said at the American Heart Association meeting that the drug allows the patient to burn brightly briefly, which I think is an apt description of what

is allowed to happen. The one drug that has shown an effect on mortality in class IV heart failure has been the angiotensin-converting enzyme inhibitors.

DR LOISANCE: You are completely right. Now, a patient is not kept on enoximone for a long period of time. If they are in stable condition at home the major treatment is angiotensin-converting enzyme inhibition.

DR FRANCIS WELLS (Cambridge, England): Doctor Pennington, I would very much appreciate some clarification. Doctor Farrar showed very nicely that he had achieved an 11% mortality after transplantation with patients that he bridged. He also showed 35% mortality before transplantation, if I understand you correctly, in patients who were bridged; this gave a total mortality of 46% in patients going through to transplantation, and that is not quite the good results that perhaps some of us are beginning to think can be expected after bridging. I would very much appreciate clarification, if you could tell me the overall mortality for patients bridged.

MODERATOR PENNINGTON: Doctor Farrar, do you want to answer that?

DR FARRAR: You are absolutely right. The overall survival rate is about 54%, which takes into consideration the pretransplantation and the posttransplantation survival. If you look at all of the centers that are using our device, it is just about the same at every center. And that is something that we found fairly interesting.

MODERATOR PENNINGTON: Well, I think this is a very important observation of course, and one that we have tried to emphasize. In fact, when we use a device to try to bridge a patient we tell the patient and the family that the chance of getting a transplant is about 50%, and that they must be prepared for the possibility of failure before we put the device in. If renal failure or an infection develops then we have to take the device out or the patient has to die with it in, but transplantation is not considered. That is a very important part of the process. Our rationale is that we would rather expend the pump than a donor heart.

SPEAKER: Actually, 65% of patients achieve transplantation. Once transplantation occurs, the posttransplantation survival is identical to that of patients who did not require mechanical circulatory support.

SPEAKER: This is an important thing to keep in mind when you are comparing with Dr Loisan's figures.

MODERATOR PENNINGTON: Absolutely.

DR JOHN WOODARD (Oakland, CA): I would just like to ask Dr Farrar if he would care to comment on the previous cardiac operation as a risk factor. Is it the excessive dissection time or is it right ventricular failure? Have you got any mechanism for that?

DR FARRAR: Only 20% of the patients have had prior operations. We have not been able to identify any particular factor. We have looked at infection and bleeding, and they do not seem to be factors. But there is nothing we have seen.

MODERATOR PENNINGTON: I might just mention that in our experience at St. Louis University the fact that a patient had a reoperation is not a factor in terms of survival, either for postcardiotomy or bridging [1, 10].

DR DAVID J. COHEN (San Antonio, TX): This question is for Dr Farrar. You showed the survival difference between male and female patients to be very significant. Is this a question of size?

DR FARRAR: No. As a matter of fact, size and body surface area were not significant. Nor were they significant in relation to the female gender.

DR COHEN: So are there other reasons?

DR FARRAR: No. I do not have an explanation except that my understanding is that in other types of cardiac surgery female patients have a higher risk. Certainly it is even more apparent in these data. Only 20% of the patients are female, so there are only about 25 patients and maybe only 10 of them older than 42 years, so these are small numbers.

DR ROLAND HETZER (Berlin, Germany): I think this was a very interesting discussion. I would like to add a few comments from our experience with 63 transplant procedures to date with an assist device very similar to the Thoratec device. In addition to the risk factors that David Farrar has shown, we have seen that patients who had pneumonia before installation of the assist system and those who had spontaneous coagulation disorders before implantation certainly had a higher risk of failure during the procedure. I assume that you mostly excluded such patients from implantation, and we certainly would be very cautious in accepting those patients in the future. Also, I would like to comment on Dr Loisan's experience with enoximone. We have close to a 200-patient experience with enoximone in patients who were referred for transplantation, and only about 60% of the patients responded well to enoximone. The others either did not respond at all or had a short recovery and then went into cardiopulmonary shock again. I would not be so extremely enthusiastic about enoximone alone, and I think you almost always should be prepared to go to a mechanical device. Also, I would like to ask a question concerning assistance after cardiomy. I think to save assist devices one should probably go to a staged procedure. That means first use a centrifugal pump. If the patient after 48 hours would be a transplant candidate or shows signs of recovery, then we would probably go to a pulsatile assist device.

MODERATOR PENNINGTON: Unfortunately, we are just about out of time. I do want to say although we did

not cover the whole topic of the postcardiotomy patient, I know we will hear more about that as the session goes on.

Panel II

Anticoagulation

Moderator: Jack G. Copeland III, MD

Panelists: O. H. Frazier, MD, Lawrence R. McBride, MD, Marko I. Turina, MD, and Christian Cabrol, MD

MODERATOR COPELAND: I think that we cannot really discuss anticoagulation without discussing hemostasis and bleeding with circulatory support devices. I would like to make a few comments before we proceed with our panel members. One thing we know for sure about our experiences with these devices is that the device interface with blood provides a constant source of stimulation of the platelet system and the clotting system. Sites of thrombus formation that have been reported include inlet and outlet cannulas, valves and valve mounts, housings, diaphragms, and the like. We have looked at platelet metabolism and found that platelets are continuously activated, presumably by their contact with the device. And if one looks serially at the β -thromboglobulin level, it is elevated. There is a continuous stimulation of fibrin metabolism. There is fibrin formation indicated by the persistent evaluation of fibrinopeptide A. Evidence of fibrinolysis in the form of XDP or cross-linked fibrin degradation products is also present.

Prevention of thrombus formation remains a problem. In 1985 we reported valve mount crevice thrombus in the Jarvik total artificial heart, and we have also seen small foci of platelet aggregations on a housing of biventricular assist devices. We use a fairly standard anticoagulation regimen for the total artificial heart, biventricular assist devices, and the Novacor left ventricular assist system. On the first postoperative day we start administration of dextran 40 at 25 mL/h and we give dipyridamole, 75 to 100 mg every 6 hours through the nasogastric tube or orally. Starting on the second postoperative day we begin administration of heparin and we maintain a partial thromboplastin time of 50 ± 10 seconds and continue the dipyridamole. By about the fifth to seventh postoperative day we switch from continuous heparin infusion to warfarin sodium, and we maintain a prothrombin time of about 18 ± 2 seconds. We continue dipyridamole administration. Any patient who has an episode that might be interpreted as a neurologic problem, for instance a transient ischemic attack, receives aspirin, 325 mg per day.

Finally, I would like to mention hemorrhage. We pre-clot the inflow and outflow grafts three times before heparinization. This takes about 20 to 30 minutes. Then we spray the outside of these grafts with biologic glue. Since doing that we have not had any serious graft hemorrhage. Before the use of this technique we commonly observed hemorrhage through the interstices of

the outflow (high pressure) graft. Thus, anticoagulation problems that I hope we will discuss today include hemorrhage, one of the major problems with each device. I think it is common, and seen in up to 30% of implants. It is often massive, resulting in tamponade. Tamponade may also occur late, weeks after implantation. I hope we will also focus on thromboembolism. If one looks, for instance, at the total artificial heart data, less than 10% of patients have embolic neurologic events and 5% have strokes with permanent neurologic damage. This may be less thromboembolism than we feared 5 years ago, but clearly there is room for improvement. To lead off I would like to ask Dr Frazier to talk. His experience has been primarily with the TCI device.

DR FRAZIER: The main problem in research in this area is the blood-biomaterial interface. We have to be concerned about that interface with any of this technology. The TCI device is designed to be minimally thrombogenic, so we have never been forced to deal with problems of clotting as much as bleeding. Bleeding has been a much greater problem than thrombus formation. Of course we completely reverse the protamine at the close of the operation, and we give no anticoagulant until the patient's condition is stabilized in the intensive care unit. At a convenient point we then start the patient on low molecular weight dextran, which is what we also use for intraaortic balloon pumps. And when the patient is taking oral feedings we start administration of dipyridamole and a low dose of acetylsalicylic acid. We really do not use heparin in the postoperative period unless the pump stroke volume becomes very low.

The lining of this pump housing is titanium microspheres. The pumping diaphragm, however, is an integrally textured polyurethane surface, which allows blood elements to catch very early on this lining. On a diaphragm taken from a 41-day patient, cells are present on the surface of the pump housing and pumping diaphragm. In a patient who has had the pump in place more than 200 days we have seen a very smooth surface with no calcification and with some endothelial cells on the surface. As far as I know, that is the first demonstration of endothelial cells cultured from an artificial surface in humans. As you know it has previously been achieved in pigs and dogs, but not in humans. These cells must be coming from the circulating blood cells.

A great advantage of this pump to date is that in more than 6 years of total use we have had only one episode of thromboembolic problems. That problem was that the

inflow cannula was kinked, leading to a distortion of the diastolic blood flow and a thromboembolic event at a little more than 100 days. But I feel very safe with this low level of anticoagulation with this regimen. We have done away with the blood-biomaterial interface.

MODERATOR COPELAND: Next we have Lawrence McBride from St. Louis University, who is going to tell us about their experience with anticoagulation.

DR McBRIDE: At St. Louis University we have used three different types of pulsatile ventricular assist devices: the Thoratec pump, the Novacor and Jarvik artificial heart. Our anticoagulation regimen in all these patients consists of starting them on dextran at 25 mL/h as soon as their chest tube drainage falls to less than 100 mL/h for 3 consecutive hours. In the interim we try to correct any coagulation abnormalities by infusing fresh frozen plasma as well as platelets as necessary. Once the coagulation parameters have been normalized, we start the patients on intravenous heparin at $10 \text{ U} \cdot \text{kg}^{-1} \cdot \text{h}^{-1}$ and we adjust the dose to maintain a partial thromboplastin time of $1\frac{1}{2}$ times normal. When the patients are extubated, and they start on oral intake, warfarin sodium is added and we attempt to achieve a prothrombin time of $1\frac{1}{2}$ times the normal. We do not wean the heparin until the prothrombin time is $1\frac{1}{2}$ times control, what we consider to be the therapeutic range. We add aspirin, 75 mg per day, only if the patient has had a thromboembolic event, or we believe that the patient is at high risk for this, such as an individual who was supported with a device who also may have a prosthetic valve in place.

As we have heard throughout the morning, bleeding is a major problem in this group of patients. Of 80 patients who were supported with devices, 42 had the device inserted with the intent that their heart would recover, and 38 patients had the device inserted as a bridge to transplantation. As one would expect, the postcardiotomy group had more bleeding and required more blood products than the bridge to transplantation group. Blood losses at 48 hours were significantly different because of wide variance from the mean. Overall, 24 of our patients required reexploration. Over the last 40, however, only 8 patients have required reexploration as we have paid more attention to correcting any coagulation abnormalities and also we have improved our operative technique, especially with clotting the graft as Dr Copeland had mentioned. As one would expect, our survivors bled less than our nonsurvivors. However this was only statistically significant in the bridge to transplantation group. In our recovery group most of these patients died of myocardial failure with multiple organ failure.

Another major problem that these patients have is thrombus in the pump or systemic embolization. In our Thoratec group of 94 devices that were explanted we found evidence of either red cell or platelet thrombus in the system of 10 patients. Nine of these patients had predisposing factors. However, 4 of the patients had mechanical disruption of their flow for a period of time. Three of the patients had major gastrointestinal bleeding,

which required discontinuation of their anticoagulation for a few days, and 2 patients had severe septic episodes. In addition to this group we had 9 patients who had either clinical evidence or postmortem evidence of having a systemic embolization. We did not find any thrombi in the nine Novacor sacs that were removed. However, 1 of our patients did have a cerebral embolus several days after implantation. This patient had multiple organ failure, had a few episodes of sepsis, and also had a serious gastrointestinal bleed for which anticoagulation was discontinued.

Interestingly, 3 of these patients had pseudoneointimal formation in the conduit, a thin layer of collagen that lined the graft. It was adherent to the graft, and we are not aware of it having caused any problems for the patients. We had 2 patients who were supported with the Jarvik heart, and we found thrombus in one of these pumps. However, unfortunately both patients had clinical cerebral embolizations.

MODERATOR COPELAND: Our next speaker is going to deviate a little bit, I believe, from what you have heard from the last three. He is Dr Marko Turina from Zurich, Switzerland, who has had extensive experience with the Carmeda process cardiopulmonary bypass, and he is going to tell us a little bit about that.

DR TURINA: I would like to tell you about the work we have been doing in Zurich and that has been taking place in Europe working with heparin attached to the parts of the pump oxygenator system and of the assist devices. There are numerous advantages if you are able to attach heparin reliably to the surfaces and not systemically heparinize the patient, or use less heparin. Of course during cardiopulmonary bypass it will reduce the blood loss. You will have less blood transfused; consequently, it will shorten the operating time. But the additional effect, which we do not know very much about, involves less complement activation and modifying immunologic response and having less anaphylactic reaction from the protamine, which can be a problem. Decreased stimulation from heparinized surfaces may decrease generation of free radicals, hemolysis, and the neutrophil activation.

We have been using in the last $3\frac{1}{2}$ years both ionic fixation and end-point fixation of heparin in the tubing and the Maxima Medtronic oxygenator with the Carmeda. We have also had coated surfaces in the Bio-Medicus pump. We have performed a prospective, randomized study which was conducted by Dr Franz Agasa, who has done most of this experimental work and has been in charge of the clinical evaluation of this work. We used the Carmeda system in a prospective, randomized way for coronary revascularization. We used the same oxygenator in both groups, giving the group with the low heparinization 100 U/kg and the full heparinization 300 U/kg. We maintained the activated clotting time during revascularization procedures of the low group greater than 180 seconds. We were not courageous enough to completely eliminate heparin. I think we will always need some heparin. In the other group the activated clotting time was

kept about 480 seconds. We were able to grossly reduce, in a statistically significant way, the loss of blood and the amount of blood transfused. Half of the patients did not need any transfusions whatsoever. So the first clinical trial has shown that blood loss can be reduced and less blood is transfused. This was significant. We found no other significant differences.

The second clinical trial used the Carmeda system devices on the roller pump and on the centrifugal pump for the resection of thoracic aortic aneurysms. Partial cardiopulmonary bypass has taken a lot of problems away when dealing with a big thoracic aneurysm, especially those extending below the diaphragm when you have to replace the whole aorta. This is our method of choice now. The only fatality that we had in this group was in a patient with a ruptured thoracic aneurysm, which are rather difficult to deal with as you all know. Of course there is a word of caution about using these heparin-coated devices, because you can generate excessive thrombogenicity, and there is a theoretical danger of the closure of the bypass grafts, especially thrombosis of the endarterectomized artery and maybe a thrombus in the mechanical valve prosthesis. We have not observed that, but there is probably a need for a minimal heparinization. We found that thrombosis in the perfusion system may occur with minimal heparinization, and therefore special techniques have to be used to keep the blood moving constantly in the perfusion system. With this technique we have found no evidence of the activation of coagulation cascade.

MODERATOR COPELAND: Finally, Dr Cabrol will give us his vast experience from La Pitié Hospital.

DR CABROL: In our hospital we are not fortunate enough to have a hematology unit. So we had to engage a colleague, Dr Szefer, who specialized in this work, and this appears to be quite satisfactory. So the total experience is now 58 patients and more than 1,000 patient-days; 1 patient has had more than 600 days on the Jarvik. As our moderator explained, the anticoagulation must prevent many problems that are shared by many devices: fibrinolysis, exacerbation of platelet function, and exaggerated coagulation. We have to stop the fibrinolysis to stabilize the blood and the functions and to balance the coagulations. Fibrinolysis is due to the transformation of plasminogen to plasmin and destruction of fibrinogen and fibrin. To measure the fibrinolysis we have some test of plasminogen and fibrin degradation products. We treat fibrinolysis using aprotinin, one million units in intravenous injection followed by a drip of 4,000 U/min.

The second problem is a strong and permanent activation of platelets. To measure this exaggerated platelet activation in vivo we use β -thromboglobulin, platelet factor IV, and platelet aggregation in vitro. We normalize platelet function using dipyridamole in big doses, 600 to 1,200 mg/day. When the platelet function is stabilized we use aspirin in very small doses, 50 to 100 mg a day.

The third problem is to reestablish the normal balance between thrombin formation and neutralization by an-

tithrombin. To correct this excess of thrombin we use heparin, 1,000 to 5,000 U/day. I must say we had no biological bleeding in that series. Of course we have some surgical but not biological; that was always controlled by the technique of our colleagues. Also we had only two thromboembolic events, both occurring in our patient who lived 600 days with the Jarvik. She had two small episodes of neurological troubles; they were very transient. Examination of the device after use showed absence of microscopic thrombi in high-risk sites like Dr Copeland said, especially around the valve, and absence of iatrogenic bleeding. Finally, the various alterations in platelet function and coagulation kinetics linked to total artificial heart implantation require permanent anticoagulation and antiaggregation as well as a suitable follow-up. The protocol must be able to explore all the systems involved to modulate treatments to individual needs.

MODERATOR COPELAND: We are open for questions.

DR D. GLENN PENNINGTON (St. Louis, MO): I would like to ask Marko Turina a question. Let me give you a situation where you, let us say, have a Bio-Medicus pump and the Carmeda-coated tubing with Carmeda-coated cannulas. You have that system ready and you put it in a patient for ventricular support. The question is as follows: How much anticoagulation would you think is necessary? Would you use none? Also, is it necessary to follow up antithrombin III levels? And if so, what are your limits? If the antithrombin III level falls below a certain level should we give heparin? What advice can you give us?

DR TURINA: I do not think that you can eliminate the use of heparin altogether, because there are the vagaries of the implantation and there are times when you are not circulating in your system. There is always the danger of thrombosis. You are also running, especially if the patient has been receiving aprotinin, through some periods when the patient is in a hypercoagulable state. So to answer it simply in a situation like this, yes. We would use the heparinization that is used in vascular surgery just as the minimum heparinization to prevent some of the possible complications. We do not have hard data to prove that, but in the animal experiments when we had been running some of these devices they have been observed without any heparin whatsoever. We observed microemboli, and that is one of the pieces of indirect evidence that some heparin should be used. Only the activated clotting time is monitored.

MODERATOR COPELAND: I would like to ask Dr Frazier a question. You said that bleeding seemed to be a problem. Is that bleeding device-related or is that related to technique? How would you go about minimizing the bleeding?

DR FRAZIER: Well, bleeding is a patient-related phenomenon. Actually, in the implantation of these devices

there is nothing intrinsically about their implantation that contributes a lot to bleeding. Obviously with the total artificial heart implantation there are long suture lines. With the left ventricular assist device, the Novacor and the Thermetics devices, the ventricular attachment is decompressed. There is no pressure. It is a low-pressure line and the aortic suture line is right in front of you. We use a woven graft and have never really had problems with the graft bleeding. So the bleeding that we have encountered has been from patients with advanced, long-standing heart failure or hepatic dysfunction; particularly more recently, patients on prolonged Inocor support with accompanying platelet dysfunction have just been a coagulation nightmare. And the bleeding is the problem, not clotting.

MODERATOR COPELAND: So you treat the coagulopathy?

DR FRAZIER: I do. I wish we had access to aprotinin because it does seem that it might help with these difficult patients.

MODERATOR COPELAND: Doctor McBride, you talked about pseudoneointima. How long had those grafts been implanted? Do you think that duration of implantation has something to do with the presence of pseudoneointima?

DR McBRIDE: The longest patient had it implanted for more than a year, and he had this fine membrane that lined the graft and was densely adherent to the graft, which did not cause a problem with the function of the device at all. The other 2 patients, if I am not mistaken, had the device in for more than a month.

DR MICHAEL ALIER (Houston, TX): I do not want to belabor a point, but what about heparin-induced thrombocytopenia in this whole group of patients who are intermittently on lots of heparin a long time?

MODERATOR COPELAND: In our own experience that is one of the reasons we try to get off. In addition, we have had trouble keeping patients even on continuous heparin infusions because of oscillation of partial thromboplastin times. That is why we tend to move on to warfarin sodium fairly quickly. Dr Cabrol, have you had any trouble with that? You keep your patients continuously on heparin for the entire time that they have the device in place. Do you ever see falls in platelet counts or do you have trouble with using heparin?

DR CABROL: Well, no. So far we do not have any problems. We use heparin intravenously for some days, and after that we use subcutaneous heparin.

Panel III

Infections—Prophylaxis and Treatment

Moderator: J. Donald Hill, MD

Panelists: Bartley P. Griffith, MD, Marco Meli, MD, and Paul Didisheim, MD

MODERATOR HILL: We have heard throughout the day the problems associated with various cardiac assist-related complications. Infection, along with multiorgan failure and bleeding, is certainly one of the major complications to contend with once a device has been implanted. Physicians have struggled with infection for hundreds of years. Our ability to treat infection has steadily improved, but it remains a struggle in certain clinical settings. Patients who receive cardiac device implants are particularly vulnerable to infection. Often they have undergone multiple, lengthy surgical procedures with extracorporeal circulation, which has a specific immunosuppressant effect. These patients come to operation with a poor cardiac output, are usually nutritionally depressed, and have tissue edema and often anemia. They then receive a foreign body implant, which involves blood transfusions. This set of medical circumstances markedly increases the likelihood of infection. We have learned that antibiotics alone are not the answer. Today, we are going to hear three reports on infection followed by a question period to try and get a sense of how we can improve the management of these patients. First, Dr Bartley Griffith, of the University of Pittsburgh, will report on their experience.

DR GRIFFITH: The problem of infection with cardiac assist devices is an interesting one, and I believe, from the Pittsburgh perspective at least, that our ability to deal with infection in this setting has improved. The improvement has occurred in part because our focus on the device has changed. Over the last few years we converted from using the biventricular Symbion total heart device to predominantly using the Novacor ventricular assist device. The change occurred on the heels of 3 to 4 years of experience with patient selection and antibiotic protocols with the Symbion heart. We experienced a high infection rate with a high mortality rate in our Symbion experience of 21 patients. Our subsequent experience with the Novacor device and change in patient selection criteria has demonstrated that the lethality of those infections has decreased and almost disappeared. This happened at a time when the Symbion duration of support was only an average of 11 days. The average implant time of the Novacor device is now in excess of 60 days.

Clearly our perspective on patient selection has changed, an example of which is a patient who was sent to us from George Magovern. The patient came to us having been on Bio-Medicus pumps, and we implanted a

Jarvik total artificial heart. It was apparent that this patient was at great risk for development of complications. Youthful enthusiasm and zeal to help this patient, who had no other opportunities for treatment, were well placed. As it turned out the patient did very well and did not get an infection, but others like him have ended up on the other end of that survival scale.

I think it is important to point out that all patients with mechanical devices tethered by percutaneous leads have problems. These patients represent a nosocomial milieu who usually are in the hospital for more than 30 days. They are kept in a recumbent position for more than 10 days; some have intraaortic balloon pumps placed, and most are intubated and have intravascular lines placed with poor pulmonary mechanics and pneumonia of a clinical or subclinical level. This setting is ripe for bacteria to develop in the pericardial space that no longer has a muscle source for host defense (the heart) but an interposed plastic device. We know from studies in our laboratory and the work of others that the polyurethane material in the Jarvik device causes a respiratory burst in polymorphonuclear cells and leaves the patient defenseless against subsequent challenges. Perhaps the complications experienced by total artificial heart candidates present a degree of complexity not experienced by patients with heterotopic ventricular assist devices. Other centers that use the total artificial heart have had better experience than ours in terms of a low incidence of infection. Perhaps there is a common ground between our rather bad experience and the very good experiences.

Turning to our experience with the Novacor, the usual sites of infection are divided into the bloodstream, drive line, mediastinum, and the device. We categorize our incidence of infection into preimplantation, implantation, and posttransplantation incidence. Seven of the 24 patients in our Novacor series had a bloodstream infection. Two of these infections occurred during the preimplantation period and were treated with intravenous antibiotics. Two patients had *Candida*, 1 of whom was successfully treated with amphotericin. The second infection occurred in a patient who had been supported by the device for 287 days and ultimately died of a sepsis and an embolus. At explantation *Candida* vegetations were found in the Novacor device. Drive line infections were infrequent and were treated with local antibiotics interspersed with occasional intravenous antibiotics. The mediastinum, once a habitual source of problems in our experience with the total heart, is no longer a major concern. In 1 patient we successfully used muscle flaps in the posttransplantation period to manage mediastinitis. The posttransplantation

bloodstream infections were by and large innocent and related to intravenous lines and were easily treated.

Our antibiotic therapy has changed over time and currently includes vancomycin, gentamicin, and selective gastrointestinal decontamination. We do this to eliminate all but the anaerobic flora. This was prompted by reports from other major transplant centers who found benefit from gastrointestinal decontamination. We observed in our Jarvik experience that most of the organisms contaminating the mediastinum were enteric in origin. Selective gastrointestinal decontamination includes colistin, nystatin, and gentamicin. This is administered to intubated patients in an Orabase formulation coating the gums and the mouth or by nasogastric tube or mouth thereafter every 6 hours for 3 weeks and then every 12 hours until transplantation. Drive lines were not a problem in the Jarvik series due, I believe, to the short duration of support (11 days on average). Our longest implantation was only 54 days. The drive line in the Novacor device is usually very firmly adherent with strong tissue ingrowth to the abdominal wall. Upon removal of the device the part of the abdominal wall attached to the drive line comes out as well.

It is very important to have a well-healed insertion site. The patients who had difficulties with infection were individuals who had skin breakdown, either from an antibiotic reaction which caused severe dermatitis or irritation from a drive line that was pulling on tissue and caused the skin edge to bleed and crust. Our drive line dressing protocol is quite sophisticated. The nurses gown and glove and perform a very extensive preparation and cleaning of the surrounding area.

Getting away from prophylaxis, if treatment is necessary it is organism-specific and, as I mentioned, for drive line infections both local and intermittent systemic antibiotics are used.

I think that available treatment and experience has improved our ability to deal with infection. My comments about the Jarvik experience are not taken out of context. The Jarvik and Novacor were not synchronous series. What we learned from the Jarvik experience has been applied to our use of the heterotopic Novacor device.

MODERATOR HILL: Next we will hear about the European experience from Dr Marco Meli of Sion, Switzerland.

DR MELI: I would like to present to you a special problem concerning the relationship between infection and organ function. There is a clinical team at the Cardiovascular Institute in Lyon that participated in the implantation of the Thoratec ventricular assist device in 35 patients who were awaiting heart transplantation in 12 different European cardiac centers. Twenty-nine patients underwent transplantation, and 21 were discharged from the hospital. Eleven patients had infections during the circulatory support period and 6 patients were infected before. The goal of circulatory support is to provide sufficient cardiac output to support optimal organ function. To evaluate the impact of infection on the restoration

or maintenance of organ function we selected 24 patients. The criteria for inclusion in this study group was hemodynamic stability and a duration of support greater than 3 days. In 23 patients biventricular support was used; in 1 patient, left assist support alone. The antibiotic protocol used in most patients was third-generation cephalosporin for 48 hours if no infection was present before implantation. If the patient was infected before implantation the preoperative antibiotics were continued and only cultured organisms were treated. The criteria for sepsis was defined as the presence of at least four clinical signs of sepsis. For each organ/system (lung, kidney, liver, coagulation, gastrointestinal tract) we chose criteria for defining failure. Using the criteria we rated the patients according to the number of organs affected and their rate of recovery.

In the 24 patients screened in this study, 16 made a complete recovery and 8 patients did not. The difference between the groups was the presence of sepsis in the patients who did not recover.

The three most important laboratory parameters were platelets, bilirubin level, and creatinine level. Platelets in the septic patients stayed less than 100,000/ μ L. In the patients who were not septic the number of platelets increased after 1 week. The same was noted for bilirubin and creatinine levels. Bilirubin and creatinine levels stayed elevated in the septic patients and returned to normal values in the patients who were not.

In conclusion, the presence of the clinical signs of sepsis is associated with a poor prognosis for organ recovery. The presence of sepsis represents a contraindication that increases the risk of organ dysfunction.

MODERATOR HILL: Finally, to present a perspective on the future and how this problem is being investigated, Paul Didisheim of the National Heart, Lung, and Blood Institute in Bethesda.

DR DIDISHEIM: At the National Institutes of Health, we have made plans for research in this area. We are optimistic about a newly launched research program on the mechanisms of infections with implanted cardiovascular devices, which I would like to tell you about.

Federally funded research and development of circulatory support systems in the United States is administered by the Devices and Technology Branch of the National Heart, Lung and Blood Institute. This includes several different totally implantable artificial heart designs that are being developed and tested. In 1989 a proposal for setting aside funds for research on cardiovascular device-centered infections was discussed among our staff and with the advisory committees to our Institute. This proposal was approved and, jointly with the National Science Foundation, in the Fall of 1990 a request for applications for research grants in this area was announced. After review by a specially convened panel of non-National Institutes of Health experts, three proposals were funded in the summer of 1991. They are from Case Western Reserve University and the Universities of Alabama and Wisconsin. The three principal investigators are Drs

James Anderson, Magnus Hook, and Stuart Cooper. They have already met and begun to discuss collaborative projects. Briefly, the objectives of the three groups are as follows.

Jim Anderson's group will examine the role of bacterial adhesion and colonization on biomaterials, of absorption of specific plasma proteins to biomaterials, activation of leukocytes, specifically neutrophils and monocytes by the biomaterials and adhesion to them, and the physical and chemical properties of the biomaterials themselves. Conditions of the study will simulate the clinical situation by using human blood, physiological blood flow conditions, clinically relevant bacteria seen in device-centered infections, and clinically relevant biomaterials.

Bacteria do not adhere directly to a foreign surface; they bind to a protein coating on the surface. Magnus Hook and his colleagues propose to isolate and biochemically characterize the ligand binding sites on the proteins that mediate the adhesion of *Staphylococcus aureus* to biomaterials. These proteins are fibrinogen, fibronectin, vitronectin, collagen, and thrombospondin. The relative role of each of these proteins in bacterial adhesion to different biomaterials will be studied. They also propose to isolate and characterize the receptors on the bacteria which bind to protein ligands. The results of these experiments will be used to design peptides that could inhibit bacterial adhesion.

Stuart Cooper's group will assess, both in vitro and in a chronic canine ex vivo shunt model, staphylococcal and neutrophil adhesion and metabolism on a variety of polyurethane materials with varying surface chemistries. The aim will be to determine the influence on infectivity of certain surface properties such as surface free energy, surface charge, porosity, smoothness, and chemical composition and the role of various epitopes or regions of absorbed protein molecules. This study should improve our understanding of the relationship of infection to thrombosis in patients with cardiovascular devices.

There are other factors not addressed by these three projects that may play a role in device-related infections; many of these have already been discussed. They include the presence of bacteria on or in the device at the time of implantation, air-borne introduction of bacteria during the surgical procedure, spread of bacteria from preexisting sites in the patient to the implant, transcutaneous access lines, the nature of blood flow, especially stagnant and recirculatory zones within the device, and the nature of the anatomical fit of the device in relation to surrounding organs and tissues. Recent improvements in device design and technique have reduced the significance of these factors. In addition, these three newly funded projects and the collaborative efforts being initiated among them should provide useful new information about the mechanisms as well as the treatment of device-related infections.

MODERATOR HILL: We will now have the opportunity to have a discussion on cardiac device-related infection. But first I would like to ask a few pragmatic questions that come up frequently. First, Dr Griffith and Dr

Meli, in a routine bridge or postoperative recovery patient, do you use any isolation techniques? I am referring to anything that is different from routine open heart surgery.

DR GRIFFITH: No.

DR MELI: It depends. In half of the patients, yes; in the other half, no. In our collaborative study each center had a different technique. I have experience with both and found no difference in the incidence of infection.

MODERATOR HILL: I think the tendency is to move away from treating these people with any special isolation technique. In my center we do not use anything that is different from our normal routine.

Second question. In a postoperative patient who is doing well, when would you remove intravascular lines as they are probably the most common source of bacteremia?

DR GRIFFITH: Usually a day too late. I think, more often than not, we leave them in too long. Our intensivists enjoy having the mixed venous saturation and the cardiac output monitored with a Swan-Ganz catheter. It is always a fight with them. But I think when patients are extubated their lines should also come out. That usually is within the first week, which is probably safe.

MODERATOR HILL: Within 7 days in a stable patient?

DR GRIFFITH: Well, as soon as a patient is stable and extubated the lines should come out. In our experience that is generally more than just a day or two.

MODERATOR HILL: Doctor Meli?

DR MELI: It is important to reduce the number of invasive monitoring lines as quickly as possible. At the beginning one prefers to maintain patient monitoring. But I think now that I reduce very, very rapidly the monitoring lines in 2 to 4 days after hemodynamic stabilization.

MODERATOR HILL: That is an interesting range. In our center in a stable patient we would almost routinely try to remove all lines within 48 hours. If there are any significant secondary organ problems you are stuck with lines.

DR GRIFFITH: How do you administer heparin without a line?

MODERATOR HILL: We do it with a heparin lock, using bolus heparin every hour.

Now regarding the question of prophylactic antibiotics, do you use prophylactic antibiotics in routine open heart operations? I think probably the answer is yes. Do you alter your protocol in cardiac device cases? I am sure everybody starts them, but do you stop them? Doctor Griffith?

DR GRIFFITH: Yes. Our protocol for gentamicin and vancomycin is only about a 48-hour protocol. We continue selective gastrointestinal decontamination until the patient undergoes transplantation and thereafter for about 2 weeks.

MODERATOR HILL: How long does decontamination of the gastrointestinal tract go on?

DR GRIFFITH: For 2 weeks after transplantation.

MODERATOR HILL: So that could go on a long time?

DR GRIFFITH: Yes, the only thing that does not continue is the Orabase, which is the coating of the gum and tongue. That is discontinued when patients are extubated.

MODERATOR HILL: What type of monitoring for infection goes on during this period of time in terms of routine cultures, white blood cell count, temperature, and clinical observation?

DR GRIFFITH: I do not know that we have anything magic—we check all those things.

MODERATOR HILL: On a routine basis?

DR GRIFFITH: We do not routinely culture. We do not get a blood culture every week or a sputum culture every week. Only if there is a clinical reason to do so.

MODERATOR HILL: Doctor Meli?

DR MELI: I use prophylactic antibiotics for only 48 hours. I only use cephalosporin; no vancomycin, gentamicin, or other antibiotics. Concerning the decontamination of the gastrointestinal tract, I am not sure one can obtain complete sterilization of the gastrointestinal tract. Perhaps it would be dangerous to use in long-term patients. This type of decontamination may only be useful for intubated patients. After extubation I think it is not necessary to sterilize the bowel. It is very difficult to obtain a complete sterilization.

DR GRIFFITH: We do not want to sterilize it. It is aerobic free and fungal free, but anaerobic organisms are really encouraged.

MODERATOR HILL: In the last 3 or 4 years there has been a lot of speculation over the evidence of a relationship between infection and thromboembolism. Either of these complications can have a disastrous effect on a patient. I would like to present a scenario to Dr Didisheim for his response, but then I would also like to hear from Dr Griffith and Dr Meli.

In a patient with a cardiac device who has an infection (a pneumonia, urinary tract infection, or even a blood line infection), would you change the patient's anticoagulation regimen?

DR DIDISHEIM: There appears to be a synergism between infection and thromboembolism. A patient who has an infection is more likely to develop thromboembolism, but in this setting there is no experience to indicate that the level of anticoagulation should be changed.

MODERATOR HILL: Doctor Griffith?

DR GRIFFITH: Succinctly the answer is no. We do not change it because we try to ride the crest of the safe and unsafe level of anticoagulation. We use heparin early and then convert to warfarin at therapeutic levels. If I knew at what site in the coagulation cascade the infection was triggered, perhaps, with some of the newer agents we could target a specific area of the cascade to block or augment its defense. I suspect there are some people who have a better understanding of this than I.

MODERATOR HILL: Doctor Meli?

DR MELI: We have only had one thromboembolic event in our series. It is difficult to establish any relation between thromboembolism and infection. We had 11 patients who were infected during the implant period and who had no thromboembolic events.

MODERATOR HILL: I would like to encourage anyone who has a question to address the panel. In the meantime I have one other scenario that occasionally arises to pose to the panel.

You are 7 days into a cardiac bridge or recovery patient. *Candida* shows up in the urine in a completely asymptomatic patient. Would you treat or not treat asymptomatic *Candida* in the urine? Doctor Griffith?

DR GRIFFITH: It would depend on the colony count. Our tendency would be to treat it with irrigation for about a week and then reassess. Otherwise, if it were a very heavy growth and we were concerned about white cells and significant hypha forms, I think we would use amphotericin.

MODERATOR HILL: Doctor Meli?

DR MELI: I have had very negative experience with *Candida*. I lost 2 patients from *Candida* infections due to colonization of the cannula. For me the presence of *Candida* in the urine or blood is serious.

MODERATOR HILL: Doctor Didisheim, do you have any other comments on the infection and thromboembolism issue?

DR DIDISHEIM: I have been impressed that the one area we thought was going to pose the greatest risk of infection—tethered devices—has turned out not to have an increased risk. I would be curious to hear Dr Griffith's and Dr Meli's opinion on whether or not they consider patients with an external pump any more at risk for infection than those with an internal pump.

DR GRIFFITH: Experience has demonstrated that for the period of time the heterotopic paracorporeal ventricles have been used (ie, an average of maybe 30 days, at least in the Thoratec series) they seem to be very safe. I was surprised by that. Our initial preference was for a totally implantable artificial heart as opposed to a heterotopic device such as the Thoratec. Our experience has taught us differently. The problems we experienced with the drive lines have been exclusively in patients who seem to have some sort of skin breakdown at the drive line exit site—dermatitis in 1 and irritation from poor tethering in 2 patients. One patient had bleeding along the exit site from pulling of the cannula, which ultimately festered and had to be controlled with local and systemic antibiotics. I think the margin of safety is fairly broad, maybe up to a year in our experience and greater in other devices that have small exit sites so long as they are well secured with good tissue ingrowth.

MODERATOR HILL: Doctor Meli?

DR MELI: I have no experience with internal devices. Using external pump devices the incidence of infection around the cannula in our series is very low, only 1 case of infection around the cannula and absolutely no infection through the skin. The problem for an internal device is mediastinitis, which is a different problem. Mediastinitis is not a problem with the Thoratec external pump.

MODERATOR HILL: I see we have a question from the audience.

DR ROQUE PIFARRÉ (Maywood, IL): I would like to just put in a good word for the Jarvik total artificial heart. At Loyola University in Chicago, we have implanted 19 Jarvik total artificial hearts. Out of these we have performed transplantation in 17 patients. We have had no gross mediastinitis in our series. The short-term mortality was due to cerebral infarcts in 1 patient and acute rejection in another. The long-term mortality was due to pneumonia in 1 patient, sepsis in another, and chronic rejection in a third. We have had some superficial wound infections that were treated locally. We have had urinary tract infections and several pneumonias, but we have had no gross mediastinitis. I think that we need to underscore the fact that the total artificial heart, the Jarvik, is a good device and can still be used very safely.

MODERATOR HILL: Your results are outstanding and you are to be complimented on them. One of the things that I recall from an early publication of yours, when I think you had 14 patients, is that many of your implants were in postcardiotomy patients who had been referred for corrections and at the same operation had a total artificial heart implant. That is a very different population than patients with nosocomial infections, often in extremis and subjected to resuscitation heroics relative to the time of implantation. Can you update that for us today?

DR PIFARRÉ: Of the 19 patients we have treated, 8 had the implantation for the purpose of postcardiotomy failure and 11 implantations were for chronic cardiomyopathy and chronic failure.

Panel IV

Management of Secondary Organ Dysfunction

Moderator: William S. Pierce, MD

Panelists: James J. Hershon, MD, Robert L. Kormos, MD,
Walter P. Dembitsky, MD, and George Paul Noon, MD

MODERATOR PIERCE: The causes of secondary organ dysfunction are:

1. Device-related complications (eg, thromboembolism, hemolysis)
2. Improper support technique (eg, use of univentricular support when biventricular is needed)
3. Patient condition before initiation of circulatory support (eg, preexisting cardiogenic shock)

Device-related complications such as thromboembolism and hemolysis are gradually being overcome and generally do not represent a major cause of secondary organ dysfunction. The selection of an improper support technique, eg, the use of univentricular support when biventricular support is required, may result in a patient who has an inadequate cardiac output or a high central venous pressure. Renal failure or hepatic failure might develop in such a patient. These problems are preventable as we gain experience. Perhaps the most common cause of secondary organ dysfunction relates to the patient's condition before the initiation of circulatory support. In a patient who has had a previous cardiac operation and cannot be weaned from the heart-lung machine, there is often a period that lasts for an hour or more while different drugs and the intraaortic balloon pump are being employed. There may be inadequate support of the circulation during this period, and the manifestation of this problem may be secondary organ dysfunction.

A variety of complications can occur during ventricular assist pumping:

- Bleeding/disseminated intravascular coagulation
- Renal failure
- Biventricular failure
- Hemolysis
- Respiratory failure
- Thrombosis/embolus
- Cyanosis/patent foramen ovale
- Mechanical failure
- Cannula obstruction/low cardiac output
- Infection
- Perioperative infarction
- Neurologic

Bleeding is a common problem after device implantation. Renal failure may be caused by a low cardiac output before implantation of the device. Hemodialysis has been required in certain patients with ventricular assist devices, but the likelihood of a good outcome is significantly reduced. Some level of hemolysis is always associated with assist pumping but is rarely problematic. Respiratory failure is a common problem and results from a group of factors relating to a high left atrial pressure, sepsis, and other factors. Thromboembolic complications are not common and may not be pump related. For instance, a patient who has a prior myocardial infarction may have a thrombus adherent to the endocardial surface of the left ventricle. This material can be cast off as an embolus and cause serious secondary organ dysfunction. The problem of a patent foramen ovale in a patient who has a left ventricular assist pump in place is a serious one. With a high right atrial pressure, blood can shunt from right to left atrium across an otherwise insignificant patent foramen ovale and result in severe peripheral desaturation. Our group, Pennington's group in St. Louis, and Frazier and colleagues in Houston have all reported on this problem. Awareness of the problem and closure of the patent foramen ovale is indicated. Mechanical failures occur but they are fortunately very uncommon. Cannula obstruction problems frequently manifest themselves as low cardiac output. As we have seen in the pictures of the different ventricular assist devices, some groups have an entire series of cannulas that have slightly different angles and different tubing sizes. You can be certain that these different cannula designs came about because of problems of cannula obstruction that have occurred. Infection has been discussed in detail in an earlier section. Perioperative infarction may be a cause of thrombus formation in the natural ventricle and a cause of thromboemboli. Neurologic events are, of course, possible end results of thromboembolic problems or may relate to low cardiac output.

We have assembled a distinguished panel of speakers. Our first speaker is James Hershon from San Francisco. Doctor Hershon has been involved in the postoperative care of a number of patients with Thoratec devices.

DR HERSHON: I would like to tell you my conclusion right now is that you cannot make a silk purse out of a sow's ear. That is basically the theme here at the California Pacific Medical Center, formerly Pacific Presbyterian, formerly Pacific Medical Center. We use the Thoratec pump as the ventricular assist device bridge to transplan-

Table 1. Circulatory Support and Hemodialysis

Group	Total	Transplanted
Patients not requiring hemodialysis	113	83
Patients requiring hemodialysis	24	8

tation. And we have had about 21 patients with this indication. I have added a couple of patients to this series who actually had mixed devices, who came to us that way. Thirteen patients underwent transplantation; there were two late deaths in that group, not related to the bridge procedure. One was due to rejection and one was due to a stroke. There are 8 patients who died before transplantation or who just were never candidates for transplantation. Those are the patients we are going to talk about.

Of those patients, 4 died of multiorgan failure including renal, hepatic, and respiratory failure. One patient died of aspiration hypoxemia. The patient never left the operating room after implantation of the pumps. As it turned out, the patient had a very difficult intubation in the cardiac catheterization laboratory, where the patient crashed after cardiac catheterization. Two patients died of a combination of sepsis and emboli. Both these patients had previous devices, one being a Bio-Medicus device. The other patient was on extracorporeal membrane oxygenation (ECMO) for 12 hours. One patient who had a biventricular assist died as a result of a right ventricular assist device thrombus. This was a patient who had a very good native right ventricle and had good flow through the native ventricle with somewhat decreased flow through the pump, and I think that was the cause of the thrombus.

Focusing on the 4 patients with multiorgan failure, I think this was a failure of patient selection. We were somewhat enthusiastic about some of these patients. Three of them had preoperative evidence of multiorgan involvement. This is always a difficult problem when you have patients in acute congestive heart failure and cardiogenic shock; whether they are going to recover after you implant devices. A word of warning, and I would add a fourth item to Dr Pierce's list of causes of secondary organ dysfunction. Avoid any patient referred from the liver service. Two of our patients had initially been referred for liver transplantations. One of them turned out to be a patient with hemochromatosis who actually had severe congestive heart failure with what was described as only mild hepatic problems by our gastroenterologists. The other patient was referred for liver transplantation but actually, as his primary problem, had cardiomyopathy and had secondary congested liver but no actual liver disease. Multiorgan failure developed in a fourth patient while he was on assist devices. He did have some mild renal insufficiency preoperatively but no other organ involvement. As you can see, acute renal failure requiring hemodialysis changes your chances of being bridged to transplantation quite dramatically. Figures from the Thoratec series (courtesy of Dr David Farrar) show the follow-

ing (Table 1). Of 24 patients in that series, 8 patients actually made it to transplantation. Sixteen patients were not able to undergo transplantation. In patients who did not have renal failure, 83 of 113 patients underwent transplantation and only 30 patients were not able to undergo transplantation. So only 33% of patients with renal failure will make it, whereas if the patients do not have renal failure 73% will make it to transplantation.

In our experience, at least in a small series, when we did place ventricular assist devices in patients with evidence of renal and hepatic dysfunction they did not improve postoperatively even though we used biventricular assist. Right ventricular failure after implantation was not a factor, as far as we know, in these patients. Obviously there is an extremely high mortality, and I think the critical thing, which is not always easy, is the patient selection that is really going to determine your outcome.

The risk factors for multiorgan failure or death are not a surprise: ECMO or mixed devices; a long cardiopulmonary bypass time in postcardiotomy patients, which may lead to multiorgan failure and infections; previous operations or multiple operations in the same sitting; and prolonged low cardiac output syndrome. One of the patients who we had with multiorgan failure had very low output preoperatively. I think we were about a day late and a dollar short in getting devices into that patient; they probably should have been put in the day before. Again, I would emphasize that I think it is difficult to prognosticate preoperatively if you do have evidence of multiorgan involvement. However, I would stay away from anybody who has an elevated prothrombin time not due to warfarin anticoagulation.

MODERATOR PIERCE: Thank you very much, Dr Hershon. Our next speaker is Robert Kormos of Pittsburgh.

DR KORMOS: I agree with most of what you just heard. I only want to make several comments with respect to the issue of multiorgan failure. As in everything in nature, timing is the critical issue. I think we are not the only people who have to deal with this problem. Of 27 patients, we have had 8 people who died on the device. Of those 8, clearly 7 died with multiorgan failure. Of those 7, just to put it into perspective from Dr Pierce's list of causes, probably 3 of those patients died because of a combination of preexisting multiorgan failure and the fact that we may have delayed in the use of right ventricular support when it was indicated, which retrospectively is more clear now than it was then. The rest of those patients died with what I believe is a sepsis-related syndrome that preceded the implantation of the device. And I think patients with many of those factors you just heard Dr Hershon talk about, patients who, for example, are autoanticoagulated, are a very high-risk group of patients. Similarly, those patients who have fevers without positive blood cultures or have elevated or mildly elevated white blood cell counts with immature forms, bands in the white count differential, are very high-risk patients. And I think they represent patients with whom

the critical care physicians are very familiar, patients with what is called sepsis-related syndrome. Only 40% of those patients will have positive blood cultures. And so you may be somewhat falsely secure in putting devices in those patients because they will have persistent multiorgan failure, at least from what we have seen, after implantation of the device. That is exemplified by the fact that many of these patients died with multiorgan failure even though their cardiac outputs on biventricular support were in the range of 5 to 6 L/min. So it is not just a perfusion problem.

There are a couple other issues. Clearly the major organs that are involved here are liver, kidney, and lungs. We have seen adult respiratory distress syndrome (ARDS), very rarely, but it does exist. And ARDS usually is associated with some kind of septic syndrome. It may relate to drugs given before implantation. For example, ARDS has been found to develop very frequently after open heart operations in patients on amrinone. We have used ECMO in the setting of a Novacor left ventricular assist device in one situation. We cannulated the right atrium and returned the flow, via ECMO, to the left atrium. That patient did well and was discharged. I am not advocating that. That is a very complex type of support. Patients with bleeding and multiple transfusions may have development of ARDS and subsequent right ventricular failure. Renal and liver failure often go hand in hand. All I can tell you is that on circulatory support, it is extremely important to lower the central venous pressure. Very commonly, even on biventricular support, there is a tendency in intensive care units to volume load these patients because they often have capillary leak syndrome. The volume that you put in tends to build up in the periphery, and you see them trying to crank up the central venous pressure and keep the volume up. It is safer, and a little bit more tricky perhaps, to use specific α -adrenergic agents to keep the mean arterial pressure up in this setting. The only thing I want to mention is that in the setting of biventricular failure and multiorgan failure we have used various dialysis-type modes to reduce the volume of the patient when necessary. But our general feeling is that once you are in a situation of multiorgan failure on this type of support, it is usually a preterminal event.

MODERATOR PIERCE: Thank you very much, Dr Kormos. Our next panelist is Walter Dembitsky from San Diego. Doctor Dembitsky has had experience with the Symbion pumps, Thermedic pumps, Bio-Medicus, Hemo-pump, and Carmeda-coated ECMO circuitry.

DR DEMBITSKY: I think as our experience with devices increases and the quality of devices improves, we will be able to select patients earlier and earlier. Hopefully we can prevent some of the multiorgan systems failure that we are encountering as a major liability of all of these devices. The one thing I think that is important in our opinion is to maintain an adequate tissue perfusion gradient. By that I mean the difference between the mean arterial pressure and the central venous pressure, which

we like to see be around 40 mm Hg. I would like to also echo Dr Kormos' admonition to keep the central venous pressure low. When we started doing extracorporeal CO₂ removal for pulmonary failure, we noted that patients would come in with arterial pressures that were adequate but very high central venous pressures as a result of the high inspiratory ventilatory pressures. Almost immediately after these patients were taken off the ventilator they would begin on a brisk diuresis. This shows how effective lowering of venous pressure is on peripheral organ function like that of the kidney. The one thing that we have done recently with our patients in multisystem failure, as you have already "bought it" once you have it, is to try and deal with the oncotic pressure. We begin early continuous arteriovenous hemofiltration, and we augment the oncotic pressure by adding albumin to these patients, believing that most of them are hypoalbuminemic. Then we can enhance the recovery phase and diminish some of the ARDS that you encounter later. When we do have a patient with ARDS we also try to look for potential causes of that: factors that overwhelm the reticuloendothelial system and the liver such as abdominal sepsis. When a patient does have ARDS and meets ECMO criteria, we have been using extracorporeal CO₂ removal techniques using the Carmeda surface with some success. We try and diminish the pulmonary insult that you produce by treating ARDS with persistently high inspiratory pressures.

MODERATOR PIERCE: Thank you very much, Dr Dembitsky. Our final panelist is Dr George Noon from Baylor.

DR NOON: The best treatment for multiorgan failure is prevention. Oftentimes we are not lucky enough to be able to prevent it. But the next best thing is the early application of the device. Also of importance in the incidence of multiorgan failure is the type of device and the situation in which we apply it. For example, those patients who are treated with emergency cardiopulmonary bypass in the catheterization laboratory or in the intensive care units have much higher complication rates than patients in whom we electively put pumps, for example, a long-term device like the Novacor. In our use of centrifugal pumps and left and right ventricular assist devices in patients, we have had experience with 125 applications. There has been a very high incidence of problems in these patients.

The causes of death are related to ventricular failure, bleeding, encephalopathy, multiorgan failure, infection, respiratory failure, acute myocardial infarction, and severe cardiac graft rejection. There are many problems that occur in these patients. The complications that occurred in the patients although not causing death include bleeding, renal insufficiency, encephalopathy, infection, respiratory insufficiency, hemolysis, and thromboembolism. Most of these are not device-related complications. These are patient-related complications. If we were able to apply the devices sooner, before these problems occurred, we would see fewer of these complications. In the Novacor,

for example, we see very few of the complications that we see with the Bio-Medicus pump. The Novacor is put mainly in patients who are in more stable condition.

Supporting patients with short-term devices, such as cardiopulmonary bypass or the centrifugal pumps, does not provide time for the patient to heal multiorgan problems that develop. For example, in some patients with the Novacor, anywhere from 2 to 3 months may be required to overcome multiorgan failure. One patient who had some pulmonary problems (tracheostomy, ARDS) took a period of 90 days to clear up his lungs.

In the management of patients with secondary organ dysfunction, the main thing is to try and prevent it with early application of the assist device. Because these devices are fairly free of problems it is better to apply them early rather than later. It is important to maintain a cardiac index of $2.1 \text{ L} \cdot \text{min}^{-1} \cdot \text{m}^{-2}$ or more while the patient is being supported to minimize the pharmacologic support of inotropic and vasoactive agents, and to optimize fluid and electrolyte balance. As Dr Dembitsky indicated, we also like to maintain a colloid oncotic pressure within normal limits. This may take a lot of albumin. We like to minimize the fluid resuscitation, especially with crystalloid. These patients can come out of the operating room gaining 10 kg or more, because of long periods of resuscitation with crystalloid. They can also obtain a lot of free fluid just from transfusions. Most of the time diuresis alone is not enough to be able to handle this large extra load of fluid that these patients have. So we, like Dr Dembitsky, like to use the continuous arterial venous hemofiltration, starting in the operating room and carrying it out into the intensive care unit, to keep these patients with good oncotic pressures and keep them from getting so much third spacing. This has been very helpful in the treatment of these patients.

Another important thing is to be able to meet their nutritional needs. Support and treat the organ systems as indicated. Employ anticoagulation as indicated for the application of the device. Maintain a good cardiac output and appropriate fluid balance.

MODERATOR PIERCE: Thank you very much, Dr Noon. Are there questions for any of the panelists? Doctor Richenbacher.

DR WAYNE E. RICHENBACHER (Salt Lake City, UT): I have a question for Dr Kormos. You made the comment that in spite of the fact that some patients have a cardiac output of 5 or 6 L/min some patients will persist in the development of multisystem failure. In the last 2 or 3 years in the critical care literature, a great deal of time has been spent looking at oxygen delivery and arteriovenous oxygen differences and serum lactate levels. It is stated that some patients who have cardiac indices of 2.2 and $2.3 \text{ L} \cdot \text{min}^{-1} \cdot \text{m}^{-2}$ still may require a higher oxygen delivery. Perhaps we should make them hyperdynamic with cardiac indices much higher. What is your approach?

DR KORMOS: As we follow up the patients in the coronary care unit, one of the things we look at more and

more is the mixed venous oxygen saturation. Some of the patients who received implants had cardiac indices that were fairly high. As they were induced with anesthesia their cardiac indices were almost $3 \text{ L} \cdot \text{min}^{-1} \cdot \text{m}^{-2}$. Yet those are the very patients who went on to have development of multiorgan failure. And when we looked at their mixed venous oxygen saturation in the critical care unit they were down around 30%, 27%, that sort of thing. So I think you are absolutely right. We are going to have to move to something like continuous oxygen saturation measurements more and more rather than just looking at simply the numbers, the cardiac index or output.

MODERATOR PIERCE: Doctor Hershon, can you comment on that question?

DR HERSHON: I am not sure that increasing assist pump flow will help you after multiorgan dysfunction has already developed, but it is an interesting concept. I do not know what other problems may arise by having much higher flows than what we normally use.

MODERATOR PIERCE: Thank you. Other questions or comments from the audience? Yes, Dr Pennington.

DR D. GLENN PENNINGTON (St Louis, MO): I wonder if you can give the criteria by which we would or would not use these systems. For example, above which creatinine level would you not use these systems? Above which creatinine level would you not implant a device? Above which bilirubin level would you say that it is too far gone?

MODERATOR PIERCE: Do you want to start it off, Dr Hershon?

DR HERSHON: I think it is very difficult to say that, as you probably know. But I think if the patient has a creatinine level greater than 2 mg/dL, I would be very concerned. And I would say this, if the prothrombin time is elevated greater than 14 seconds, I would be extremely concerned about putting devices in that patient.

DR PENNINGTON: How about bilirubin? Is that a factor?

DR HERSHON: I do not worry about bilirubin too much.

DR KORMOS: If the initial creatinine clearance is in the range of 25 or 35 mL/min, which it can be in some of these chronically ill patients, then I think if you see a creatinine increase from 2 to 3 mg/dL, that is an extremely bad situation. On the other hand if you have normal creatinine clearance and you see a creatinine bump from 2 to 3 mg/dL, the patient will tolerate that kind of insult. So that is why it is very difficult to set those limits. But I think, by and large, if we see creatinine levels in general greater than 3 mg/dL, I would be very concerned and I probably would try other forms of support to see if I could restore

renal function before I went on to one of these more complex devices. I think if the bilirubin level is greater than 4 mg/dL, 4 to 5 mg/dL, I am probably not going to put a device into a patient.

MODERATOR PIERCE: Doctor Dembitsky, would you comment?

DR DEMBITSKY: Well, I think it depends on whether the patient has chronic or acute disease. If the patient has chronic liver failure and then you are faced with a high bilirubin level, I think that is a contraindication probably in the long run. But in our experience we have put devices in successfully and had native heart recovery as well as successful bridge to transplantation with creatinine levels greater than 5 mg/dL and patients acutely ill, and bilirubin levels greater than 5 mg/dL. I think it depends individually on each patient. It is very difficult to select a single number.

MODERATOR PIERCE: I think that is a very important point. Doctor Noon?

DR NOON: We make the decision to implant a pump on an individual basis, carefully evaluating each patient. But in most patients with a creatinine level greater than 3 mg/dL we are very cautious about putting a device in.

MODERATOR PIERCE: Okay. Thank you very much. Doctor Wolner.

DR ERNST WOLNER (Vienna, Austria): I am a little bit surprised that none of the panelists has discussed the relation between multiorgan failure on one side and infection on the other. It seems, in our experience, when you have a proper functioning device and a good cardiac output, you can control renal failure. You can control some hepatic failure and also respiratory failure, as long as the patient does not have infection. When the patient has an infection, then usually multiorgan failure develops. My question is: In how many of your patients, Dr Noon, in whom you have observed multiorgan failure have you observed additional infection? In our experience, the main problem in multiorgan failure is the additional infection.

MODERATOR PIERCE: Thank you very much. Doctor Noon, do you want to comment on that?

DR NOON: I cannot give you the exact number, but I agree with you that most of the patients who do have multiorgan failure, because of such things as metabolic changes or lowered resistance, end up with infection. I am not sure whether infection is the cause of the multiorgan failure. I think it is the other way around.

MODERATOR PIERCE: Doctor Hershon? Comments?

DR HERSHON: I think that many of these patients ultimately die of infection because they have multiorgan failure. It is the same thing with people with ARDS, who do not die of respiratory failure, they die of something else, usually infection. Lactic acidosis develops in these patients, and they look septic near the end. We never culture anything out. They are on antibiotics and so on. They may well die of infection. But I think if they have multiorgan failure it is very difficult to reverse even with good cardiac outputs.

MODERATOR PIERCE: Okay. Thank you very much. Doctor Meli?

DR MARCO MELI (Sion, Switzerland): The relation between infection and multiorgan failure is fundamental. In our series we have obtained complete renal recovery with return to preoperative values of creatinine in patients without sepsis, without infection. But in patients with sepsis, this recovery is partial or not present. Patients have been maintained with hemodialysis for 3 weeks on assistance without increasing the morbidity and the mortality. In our experience, a value greater than 3 mg/dL for creatinine is not a contraindication.

MODERATOR PIERCE: All right. Thank you very much. Well, I think we are all in agreement that we would like to select our patients very carefully, implant the devices early, and hope that we can minimize the secondary organ dysfunction. I would like to thank the panelists for their very interesting contributions and the audience for their participation.

Panel V

Long-Term Biventricular Assist

Moderator: Charles-Julien Hahn, MD

Panelists: William S. Pierce, MD, Don B. Olsen, DVM, Kenneth Butler, and Robert T. V. Kung, PhD

DR PIERCE: I am going to discuss an electrically powered artificial heart that we have been working on for 8 years. It is placed in the chest in the orthotopic location, and the electric motor and motion translator, which is a device called a roller screw, is positioned between the two ventricles. These are pusher plate activated ventricles. We have to have all of the component parts that most of you are familiar with. Because this is a closed nonvented system, there has to be a compliance chamber in the left thorax. The electronic control system and emergency implanted battery system is placed in the subcutaneous position. And, of course, energy is transmitted with the wireless technique of inductive coupling with a primary and secondary coil and then an external battery pack. I think most of you are familiar with the overall design principle.

On cross section of the artificial heart, there is a pusher plate located at each end. There is a fixed distance between those pusher plates. In other words, they are attached but they are not attached to the blood sacs. The rotor of the motor is attached to the nut of the roller screw. As this motor rotates some four or five revolutions in one direction and then counter rotates, the pusher plate moves back and forth a distance of about 2.5 cm. The two main items of the prime mover and motion translation system are the brushless direct-current motor (Saracen) and the stainless steel roller screw (SKF transroll). These devices are widely used in the machine tool industry, and they are also a component of the wing flaps of the Concorde. Any of those of you who came to the meeting across the ocean in the Concorde, the SKF roller screws actuate the wing flaps on that plane.

Thus the components include the motor and motion translator, biomer polyurethane blood sac, and the polysulfone end caps, left and right. We use Björk-Shiley tilting-disc valves. The implanted batteries are designed to provide about 45 minutes of energy to the pump if the primary and secondary coils are separated. Because gases can diffuse in and out of the compliance chamber, we have to have some sort of a port through which we can access that compliance system and measure the gas pressure and change that pressure in accord with the needs of the device.

In the laboratory, the first designed pump that we worked on instead of using a roller screw motion trans-

lator used a drum cam having three cam followers. We had pretty good luck with 1 of those animals, but we had quite a bit of problem with the mechanics and with the little tiny cam followers. We subsequently abandoned that system and began to use the roller screw system. And we are starting to have a little better luck with our animals; 1 is still going and has passed the 11-month mark.

In the design of the animal experiments, we use closed systems. The pump is placed in the thorax as is the compliance chamber and battery pack, or we use an implanted battery and control system, the energy transfer system, a subcutaneous access port to get into the compliance chamber, and the external battery pack, or, of course, most of the time the animal is just kept on the house electrical supply.

At 200 days after implantation, the animal weighs about 103 kg and the pump handles about 10.5 L of blood per minute. The animal has a very low venous oxygen saturation as you might expect. But he still eats vigorously and actually looks pretty good. So we are very, very encouraged about this. This particular animal did not have the energy transfer with the coil arrangement, but the ones that we are doing now do have that system. So we are looking forward to doing an additional series of animals and see if we can continue the record of having animals that will last for a long time. Our next speaker is going to be Dr Don Olsen, and we will hold our questions until the end.

DR OLSEN: The University of Utah and Institute for Biomedical Engineering has been working on an electro-hydraulic artificial heart now for about 4 years. And in concept we have the following: internal batteries, internal electronics, and the TET telemetry coil system, with TET meaning transcutaneous energy transfer of power to the induction coil system. Our internal batteries are supplied by the consortium group between Ottawa Heart Institute and the University of Utah, and we are very pleased with that. The entire intrathoracic components all fit within the pericardial sac. We do not have a volume displacement or compliance chamber in our prototypes presently. We have always strived for simplicity and miniaturization. We have a titanium encasement. There is a brushless direct-current motor housed within this containment with the electrical pass through for back EMF control of the commutation. The axial flow pump reverses such that the hydraulic oil flows back and forth between the right and

left ventricle, coupling the right and left ventricle both volumetrically as well as in timed sequencing.

Our test model that we have been using in a series of acute calves is the Utah 100 type artificial heart. Actually this is an 80-ml stroke volume device. Today I would like to address how we achieve balance in this coupled system without external ports and without a volume displacement or a compliance chamber. We do that by making a small atrial septal defect here between the right atrial cuff and the left atrial cuff. This, then, is a small-diameter, and we will talk about that orifice that allows a volume of blood to move back and forth.

Our surgical procedure is the following. First we expose the natural heart, do our cannulation, and establish the cardiopulmonary bypass. Then we do the cardiectomy. We make sure of hemostasis then. We now are measuring through our heart-lung machine the systemic flow of the calf. But we are also able to measure the amount of bronchial flow return into the left atrium. We use this measurement in making a decision on which of the predesigned and prebuilt intraatrial septal orifices to use in these atrial cuffs. Then we go ahead and surgically implant the device and wean the calf from the cardiopulmonary bypass on to the electric powered artificial heart.

The purposes of the *in vivo* acute experiments were the following: to establish the intraatrial shunt performance, verifying that we can indeed achieve ventricular balance and that we maintain patency of that atrial shunt; to look at the hematological effects, hemolysis, and thrombus formation within the device and all of its components and attachments; and to examine the electrohydraulic TAH 20 system's performance both in regard to the fit anatomically and in regard to the physiological performance as far as adequate cardiac output is concerned.

In a series of 6 calves the measured bronchial blood flow as a percent of the flow of the cardiopulmonary bypass machine goes from a low of 5% to a high of 17%. We have learned that in those calves that exceed 12% we have a difficult time in establishing balance. The shunt size that we have selected to implant with each particular bronchial flow has been narrowed down to two sizes; we avoid putting the electrohydraulic artificial heart in a calf that has a high left-left shunt. During the course of the experiment we have measured the left atrial pressure and subtracted from that the right atrial pressure giving the change in pressure across this intraatrial shunt. We find that the highest we had was 6 to 10 mm Hg and the lowest we had was 2 to 5 mm Hg. In the longest living calf (about 9 days), the average difference between the mean left atrial pressure and the mean right atrial pressure was about 3.5 mm Hg, greater on the left than on the right. Occasionally we would have some spikes in pressure difference. Presently our motor speed control algorithm is being addressed to see if we can minimize these spikes, but they are relatively transient. Part of it I think might be a hammer effect from the method of open port measurements that we employ.

On the bench we tried to look at some of the flows using contrast media. This shows quite readily that we do

have that shunting. There is a higher shunt from left to right than the reverse. In the calf who lived 9 days the left atrium and the orifice of the small intraatrial shunt were quite clean.

The conclusions from these 20 *in vivo* experiments were the following: The intraatrial shunt provides adequate balance throughout a variety of bronchial blood flows. The intraatrial septal shunt has shown no evidence of thrombosis or occlusion, albeit so far our longest experiment was 9 days in these acute studies. The size constraints of the animal do exist and can affect the cardiac output and device performance even in our miniaturized system. Furthermore, we have had no evidence of intraventricular thrombosis formation except in one experiment where we had an electrical device failure and stoppage of the device without adequate heparinization. These experiments have been a great learning experience, resulting in 18 design changes. The system meets the physiological demands with its automatic control algorithm.

Now we have made a totally integrated device. This device is being built now for animal testing; it has an 80-mL stroke volume and will fit totally within the pericardial sac. Doing extensive fit trials we have successfully fit this clay model into a 57-kg and a 68-kg cadaver, although the 57-kg cadaver did have cardiomegaly. But it does fit well. We also have successfully fit the model with slight modification of the length and angulation of the inflow outflow ports into a 75-kg sheep and an 80-kg calf. This device will have an 80-mL effective stroke volume. Presently we are preparing for additional animal, cadaver, and human intraoperative fit trials.

MODERATOR HAHN: Thank you so much, Dr Don Olsen. Now I will ask Mr Ken Butler to give his lecture.

MR BUTLER: Indeed it is a pleasure for me to be here representing my colleagues at the Cleveland Clinic and my co-workers at Nimbus and present to you a run down of our particular artificial heart device that we have been working on for the last 4 years.

From the anatomical view, central is the blood pump energy converter unit that fits in the chest, replacing the natural heart. Our system is a dual pusher plate and it does have to have its compliance space managed; we do this with a flexing diaphragm chamber that is connected via a duct to the interspace. Gas is transferred back and forth between the interspace of hemodiaphragms and the flexing chamber, which faces into the lung space. We also have refill port that is accessed percutaneously.

The main power is derived from primary batteries that are located on the outside, and we also use a TET system including the secondary coil, which is implanted subcutaneously over the left chest. We are using the Thermedics or Thermocardiosystems version, and it has a secondary coil that fits on the outside over that. That transmits alternating current power across the skin, which is then conducted down to what we call a power module, which

is actually a rectifier that converts the current into direct-current power, which then drives the energy converter. The electronics package in our system is contained within the central blood pump and energy converter. An appendage is the internal battery, which is connected into the power module. The power module also serves as a connecting point for the various cables. So you can remove the internal battery and remove the secondary coil without disturbing the energy converter.

The blood pump itself is in the "human configuration" as a result of extensive anatomical studies conducted at the clinic, where every dimension was critically evaluated to make sure it would fit in a maximum number of adult patients.

The blood pump energy converter has been our main focus of work over the last several years. This is an entirely new design for us. Although we have had a considerable amount of experience with left ventricular assist systems using actuation and energy converter technology, this is really a new departure for us. The energy converter is contained within a titanium superstructure. The ventricles themselves are made of a carbon-impregnated epoxy, which has saved us a considerable amount of fabrication complexity, and they certainly are lighter than our titanium castings. There is a dual pusher plate. We simply rely on an alternate ejection from the left to the right. While the actuator is engaged in ejecting on the right side, the left side is free filling. The pusher plates, when they are filling, are disengaged from the sac or the rolling diaphragm. Conversely, on the right side when it is ejecting on the left it is filling on the right. So our control system essentially is to match our actuator cycling frequency with the fill rate of the blood pumps. If we go too slow we will impede filling. If we go too fast we will actually start an ejection while one of the ventricles is filling. So all we have to do is match our motor speed to the fill rate. And we do that electronically with a rather simple system, which I do not want to get into here.

The energy converter is based on an electric motor continuously driving a gear pump that puts out a flow of hydraulic fluid. That fluid cycles a piston back and forth in a container, which provides the actuation. We have a mainspring in the device that gives up force when it is ejecting on the left side and is cocked when the right side is ejecting. So it evens out our power distribution.

The diaphragms are the flexon rubber that the Clinic has been using for years. And we do use the biolyzed coatings that the Clinic has developed on all the blood contacting surfaces.

This is the book on our system as far as the key characteristics. I think all the systems are coming to about these weights and volumes. Our capacity is a 60-mL blood pump. It can generate up to roughly 10 L/min, 60 beats per minute. The direct-current power consumption at its maximum is 15 W. Our internal battery time, based on our latest tests, is in excess of 60 minutes, and that is at a 6 L/min condition; that is specified for the internal battery.

We have been concentrating the last few months on in

vivo tests, and I would like to focus the rest of the presentation on that, which gives you some idea of how these systems work and possibly some of the problems that we have with our animal models as has been alluded to before. We normally are using 80-kg calves. We are focusing just on the central blood pump and energy converter. We are using external electronics and a vent for compliance. Basically, what we are trying to show that we can support one of these animals and that the system is compatible with the physiology. And of course, most important, we are using it to test our system. We have done four experiments to date and our progression has gone from a planned 1-day acute model to a couple of intermediates, and our last one was 45 days.

On these early animals we are using all the blood pressure instrumentation we need: inlet and outlet pressures on both sides. These animals therefore are fairly risky in that there are indwelling catheters in them. One of the things we have learned over the years is that a calf is not a human, and it is very difficult to take a human configured system and try to force it into a calf. Therefore we have changed the inlets a little bit to help us get better anatomical fit in the calves. The big difference is that the outlet on the left side is bent so it intercepts the aorta.

I would like to give some data now from a 45-day experiment. When we plot out all the data points we took, they average around 10 mm Hg in the right atrium. On the left side it is a little more scattered, but it would average out about 16 mm Hg. One of the things about these animals, and in particular one, he maxed our pump out the first night. He was running at 10 L/min essentially on day 1 and that is where he stayed. Although this is a good healthy workout for our actuator, it does not do much for our control system, which indicates a problem we have in the model. We maxed out at 160 beats for the whole experiment and our power draw was 15 W throughout. In some of the earlier experiments where the calves were not as healthy, we were able to go to the lower flow rates and verify that indeed our control system does function like we intend it. But we need to have a lot more experience with that.

To summarize the in vivo results, we can maintain the hemodynamics of these animals. The fit is extremely good. We have not had any hemolysis or thrombus problems. The diaphragms come out absolutely clean after the experiment. What we are going to be doing is continuing the in vivo studies, our sequence of involving the other system integration elements. This is due to come in a couple of months. We will add that into the energy converter, add the compliance TETs in with the rest of the systems, and by the end of this program we will be doing a total.

I think I speak for all of us when I say that these programs are supported by the devices and technology of the National Institutes of Health, and as I understand the plans we have another couple years to go on the current contracts. There probably will be a follow on for 3 or 4 years, which puts us in a time frame such that we probably would be ready to use human implants on a trial

basis somewhere in the year 2000. That is the time line we're working on.

MODERATOR HAHN: Thank you so much, Mr Butler, for this extremely nice presentation. Now we will ask Dr Kung to come here and give his report.

DR KUNG: This is a collaborative effort between Abiomed and the Texas Heart Institute on the development of the electrohydraulic total artificial heart. Because I am last on the agenda I thought the best thing for me to do is to focus on the specific and unique features of our system instead of going into the description of the entire system.

External parts of the system are battery electronics including a TET, internal battery, blood pump, energy converter, hybrid electronics, and sensors for the control of the system. I will describe how our energy converter works, how our blood pump interfaces with the atria, the design of the inflows for the pump, and how the compliance or rather the management of the left and right flow differences is done. I also will give some information on our *in vivo* results.

The system is electrohydraulic, and the difference between our electrohydraulic system and that of Nimbus, which I can describe as also electrohydraulic but electrohydraulic converted to mechanical energy, is that we use a direct electrohydraulic drive of the flexing membrane, which is what the Utah group does also. The difference between our system and the Utah system is that we use a unidirectional rotary pump. In other words, the rotary pump is not reversed on every cycle. Fluid reversal is accomplished through an electromagnetic fluid valve. The blood contacting part of the system is designed to be smooth and seamless, and it uses angioflex, which is a polyurethane proprietary to us, and also trileaflet valves made of the same material. We use blood as the volume compensation: I believe we are the only ones taking that approach.

As you heard yesterday, if you have a biventricular support system—in this case this is also classified as biventricular—you have to make sure that the left flow and the right flow somehow match or the difference matches the bronchial shunt. In current systems that have been used clinically you have to manage this by essentially dialing in the flow so that you do not flood the lungs. When you flood the lungs that means the right side is flowing too much. One of the manifestations of that is that the left atrial pressure goes up. If the left atrial pressure goes up you can think of a way of using that as a means of feeding back to your system.

Because for a total artificial heart you obviously cannot keep on dialing the right side flow, you have to use what physiological information is provided by the artificial heart and the living system to control or feed back to adjust the right side flow. There is a hydraulic pump with a fluid switch that switches the fluid back and forth. To manage the left and right side flow, we have put a shunt flow in the hydraulic circuit and placed that in reference to

the left atrial pressure, which means that you can put a flexible diaphragm in contact with the left atrial reservoir. If the left atrial pressure goes up the shunt flow increases in the hydraulic circuit. When the shunt is larger to the right side of the hydraulic chamber, it reduces the amount of blood that is being drawn into the right-sided blood pump. So as the left atrial pressure goes up there is less stroke volume on the right side, and as the left atrial pressure goes down there will be more right-sided stroke volume. One of the advantages of this is that the flow compensation characteristics would not vary over time. In long-term studies we are trying to demonstrate some of these characteristics.

I would like to talk a little bit about the control algorithm. With it we have taken a very simple approach to control the system. In the hydraulic circuit there are pressure transducers, one pressure transducer that measures the filling pressure during the fill cycle of either the left side or the right side. That information is used to control the hydraulic pump. If you have a high end-diastolic pressure on one beat it senses that pressure and then it tells the pump to go to pump a little bit harder on the next beat, so you are trying to bring the end-diastolic pressure to a level that you have preset, whether it is zero or some number that is close to zero filling pressure. The control algorithm is also responsive to afterload because the afterload changes affect the pumping rate or the filling rate. Once you change the filling rate you change the end-diastolic pressure, which then is sensed again, changing the pumping speed of the rotary pump. The other control is focused on trying to make every stroke a full stroke. We have an optimal sensor in the system that monitors the diaphragm position. That information is then used to determine the beat rate of the system. If there is a lot of fluid or if the atrial pressures are high, the beat rate will increase to maintain the full stroke and at the same time to try to bring the end-diastolic pressure down.

Now let me go to the energy converter. There are two channels that connect the hydraulic chambers to the energy converter chamber, so the flow of hydraulic fluid can go either way on each beat. It reverses the flow. As I say, there is a unidirectional rotary pump and a centrifugal one pumping hydraulic fluid. There is a switching valve concentric to the pump that assumes two different positions, which then opens a set of ports, which then directs the flow either from one pump to another or vice versa. It is actually a very simple system. You are switching the hydraulic chambers, which pumps the blood to the two alternate pumps. This is an alternating pumping system.

Now let me describe briefly the blood pump. The valve that is used is a polyurethane trileaflet valve. Concerning the experience that we have on these blood-contacting components, the valves have gone about 400 million cycles *in vitro*. The pumps we have tested up to 100 million cycles, and *in vivo* about 150 days.

The design of the whole system is to achieve a seamless blood contacting surface. Now in the inflow region, where you have tissue and cuff in contact and sutures that hold the cuff and the tissue together, because we have

discontinuities, it is much better to have a cuff that can promote growth of tissue. But to avoid ingrowth into the inflow of the device, we have made a rough surface on the cuff and a smooth surface in the device. The cuff will be sewn onto the atrial remnants and then the rest of the device will be snapped into the atrial cuff, so this is a quick connecting approach. By this approach there are no end-to-end seams. To get around this rough and smooth configuration, we actually have a smooth surface tube project into the atrial cuff. This provides a tissue barrier to stop the growth of tissue. It is helped by the fact that you have flow going in this way and you probably have some recirculation, which prevents tissue from climbing up the smooth step. The protrusion into the atrial cuff is about 3 mm in height, and in *in vivo* studies it does act as a barrier quite well. It essentially tries to keep away blockage problems.

The system actually can operate at more than 8 L/min, but at 8 L/min it takes about 20 W.

In our chronic studies, we will concentrate on system integration; we will include hybrids, TETs, and *in vitro* study as well as the liability evaluation in this program.

MODERATOR HAHN: Thank you for this very interesting lecture. There are plenty of problems we could discuss, but first I should like the audience to ask questions, because the time is extremely limited.

DR D. GLENN PENNINGTON (St. Louis, MO): I would like to ask Dr Pierce about those animals that he showed us. What is the stage of development of those animals? Is that an integrated system? In other words, are those implanted electronics? And is that an implanted compliance chamber? How complete is the system we are seeing in those animals?

DR PIERCE: Well there is really a progression. As I mentioned, the animal that is now over 11 months does not have energy transferred by the coil system. We do have another animal that we have subsequently operated on that has implanted batteries, a closed system, and energy transfer by the primary and secondary coil. The only thing that we are lacking now is the ability to talk to our system and get information in and out of it. Other than that, the system is pretty much complete.

MODERATOR HAHN: Another question? Doctor Champsaur?

DR GERARD CHAMPSAUR (Lyon, France): What is the projected price of the total artificial heart using your current techniques?

DR KUNG: All of us probably will have an answer to that. Let me just start by saying that we have in the design of the system and its development always tried to make it

simple enough so that things are not that expensive. Our estimate is that we can do it, once the whole technology is developed, for about \$25,000. Now I am sure that some of the people here would think otherwise, but we have done some evaluation of that.

MR BUTLER: In our particular case, we project a cost between \$35,000 and \$50,000. Actually, our total heart device is cheaper than our left ventricular assist system because it is simpler.

MODERATOR HAHN: Doctor Olsen, do you have a comment?

DR OLSEN: I think when we consider the additional constraints and costs of Food and Drug Administration approval, it will be the upper limit of Mr Butler's estimate of \$50,000.

DR PIERCE: I think it is important to note that there is nothing inherently expensive about these devices. The roller screws we use in our units cost, I think, \$1,000. The motors are \$400 or \$500, and there is one fairly complex titanium machined part, the costs of which would not be high if you were going to make a bunch of them. But by the time you put in the animal experiments and all of the careful controls that have to be done before something like this can be sold, the price escalates. I would estimate \$50,000, something like that, and I do not think these total hearts are going to be more expensive than the left ventricular assist devices. There is very little additional complexity to them.

MODERATOR HAHN: Another question?

DR PAUL DIDISHEIM (Bethesda, MD): I would like to ask each of the panelists about thromboembolism. Because we know from past experience that an implanted device can look free of thrombus or relatively free of thrombus and still be a generator of thromboemboli, I would like to ask each of the panelists if they have yet had an opportunity to look at end organs, specifically the kidney, which has in the past been a useful thromboembolus trap.

MODERATOR HAHN: Doctor Kung, would you answer?

DR KUNG: Yes, in our experience, we have not had any long-term experience with the total artificial heart yet. But the technology that we have used in the permanent ventricular assist device is really quite similar to what we have here. And there we have had experience up to 5 months with no infarcts or emboli.

MODERATOR HAHN: Another comment from the panelists?

MR BUTLER: We just completed a 45-day experiment with the total heart. That is our longest. But it does have the biolyzed coating that we have had considerable experience with on the left ventricular assist devices. This 45-day animal was run without anticoagulants, and I do not think all the histology data are in yet, but the gross examination showed no infarct problems.

DR OLSEN: Our limited experience in acute experiments with the electrohydraulic system would not lend itself to respond there. We have seen none, however, in 9 days.

MODERATOR HAHN: Doctor Pierce?

DR PIERCE: If we follow the design principles that we have all learned the hard way over the past 20 or so years and then we keep our animals on warfarin sodium and their renal function has been basically normal, the devices have been clean when they have been taken out. So thromboembolism has not been a problem in our case. We have had broken wires. We have had moisture get into the devices. We have had just about everything you can think of. But thromboemboli have not been a problem.

MODERATOR HAHN: I guess I must stop this session. It is a great pity, because we had so many questions to ask about these electromechanical devices that will be the future in cardiac replacement.

Circulatory Support in Infants and Children

D. Glenn Pennington, MD, and Marc T. Swartz, BA

Department of Surgery, St. Louis University Hospital, St. Louis, Missouri

Although the last decade has brought dramatic improvement in patient selection and postoperative management of adults and children undergoing advanced mechanical circulatory support, technological advances have been largely limited to the adult population. Intraaortic balloon pumps are technically feasible, but their efficacy has been questioned and their use has been limited in children. Over the last decade, extracorporeal membrane oxygenation has become the most commonly used method of mechanical circulatory support in children who have severe cardiac failure after cardiac operations. Additionally, a small number of infants and children have been supported with extracorporeal membrane ox-

ygenation as a bridge to cardiac transplantation or as temporary support during reversible myocardial failure due to lesions such as viral myocarditis. More recently, a small number of pediatric patients have been supported with centrifugal and pneumatic devices, particularly after cardiac operations. Surprisingly, many of these patients did well with left ventricular support only. The overall children's survival rates in the myocardial recovery group are better than those in adults. However, current pediatric devices do not provide support for greater than a few weeks, making bridging to transplantation less feasible than in adults.

(*Ann Thorac Surg* 1993;55:233-7)

Circulatory support of patients with failing hearts has been a goal since the 1950s, when Stuckey and associates [1] used a heart-lung machine to support patients with cardiogenic shock after myocardial infarctions. Subsequently, Dennis and co-workers [2] used a left heart bypass system in 2 patients. One of the early attempts at supporting a child occurred in early 1963, when Spencer and colleagues [3] supported a 6-year-old girl in whom severe cardiac failure developed due to pulmonary hypertension after repair of a ventricular septal defect. Apparently she was successfully supported with venoarterial bypass for a period of hours, but died of arrhythmias 24 hours later. In 1967, DeBakey [4] supported a 16-year-old girl with a left atrial-axillary ventricular assist device for severe cardiac failure after mitral valve replacement. The device performed well and she was a long-term survivor. Subsequently, circulatory support of adult patients has been accomplished with an array of devices for cardiac failure after cardiac operations, for acute myocardial infarction shock, and as a bridge to cardiac transplantation [5]. In spite of the development of more sophisticated devices for adults, the need for miniaturization of these devices has delayed their use in children. This report reviews the current systems available for children and summarizes the clinical results.

Some of the data contained in this article were obtained from the Registry for Mechanical Assist Devices and Total Artificial Hearts sponsored by the American Society for Artificial Internal Organs (ASAIO) and the International Society of Heart and Lung Transplantation (ISHLT) and reports from the Extracorporeal Life Support Organiza-

tion. Figure 1 shows the number of cases of advanced mechanical circulatory support in children per year, from 1981 to 1990.

Intraaortic Balloon Pumps

Since the pioneering work of Moulopoulos and associates, who introduced the use of counterpulsation by means of an intraaortic balloon in 1962 [6], the intraaortic balloon pump has been the primary method of mechanical support of adults with cardiac failure [7]. Although the use of intraaortic balloon pumps in children has been limited, it has been effective in some cases [8-10]. In a 10-year experience at the Toronto Hospital for Sick Children, 38 patients received intraaortic balloon pumps, with 14 survivors, for a 37% overall survival rate [10]. Recently, Christensen and associates [11] of Primary Children's Hospital of Salt Lake City, UT, reported the use of intraaortic balloon pumps in 29 children, 12 (41%) of whom survived. Their survival rates were highest in children older than 5 years. Of 10 infants treated with intraaortic balloons, 2 survived. Near systolic or suprasystolic diastolic augmentation was achieved less often in children younger than 2 years. Del Nido and colleagues [10] reported the successful use of an intraaortic balloon pump in a 2-kg infant. However, from the Utah experience [11], one would conclude that the outcomes are less favorable in younger patients. In the Toronto series, all 4 children younger than 5 years died, but their experiences occurred before the miniaturization of the balloons [9]. The effectiveness of intraaortic balloon pumps is still limited in small children and infants by increased aortic elasticity, rapid heart rates with small stroke volumes, and difficulty of insertion. Furthermore, the intraaortic balloon pump is often ineffective in patients with predominant right heart failure, which often occurs in children with congenital heart disease. Therefore, it is our opinion

that if intraaortic balloon pumps are to be employed in infants and children, a more complete form of circulatory support should be available to augment or supplant the intraaortic balloon pump if it does not provide optimal support.

Extracorporeal Membrane Oxygenation (Venoarterial Bypass)

The use of venoarterial bypass with an oxygenator for prolonged circulatory support has generally been referred to as "extracorporeal membrane oxygenation" or ECMO. Use of this technique was reported in patients with severe cardiac failure in 1957 and 1965, but it was not commonly used during the 1970s. Indeed, in the National Heart, Lung and Blood Institute-sponsored study of the use of ECMO for severe respiratory failure, patients with concomitant cardiac failure were excluded [12]. Simultaneously, a large, successful experience with the use of ECMO for infants with severe respiratory failure was developed by Bartlett and colleagues [13]. In their experience, the early results of ECMO for postoperative cardiac failure were disappointing [13]. However, subsequent experience demonstrated the effectiveness of ECMO in some postcardiotomy patients. In 1982, we initiated an ECMO program at Cardinal Glennon Children's Hospital of St. Louis University to support children after cardiac operations. Of 65 postcardiotomy patients treated with ECMO for cardiac failure over the ensuing 9 years, 44 (68%) were weaned from the ECMO circuit and 23 (35%) were long-term survivors [14]. During the last 3 years in which 26 postcardiotomy patients were treated with ECMO, 20 (77%) were weaned and 13 (50%) survived [14]. In our series of 65 patients, the most common complications were bleeding requiring reexploration (44 patients), sepsis or mediastinitis (20 patients), neurological complications (18 patients), and renal failure (25 patients). In spite of this high complication rate, survivors have generally done well after hospital discharge. We

have been unable to determine which pre-ECMO factors would ultimately determine survival after placement on ECMO. Although it is clear that some cardiac defects are so severe that survival is impossible, this is not often known at the time the decision to use ECMO must be made.

A review of the literature (Table 1) reveals a rather wide range of survival rates from 30% to 70% in infants and children undergoing ECMO support for postcardiotomy heart failure over the last 10 years [14-18]. Although early survival rates were less than 50%, rates during the last 3 to 5 years exceed 50% in some centers [14, 16-18]. However, in a larger collective series of 453 pediatric patients supported with ECMO for cardiac failure, the "survival rate" was 43%. These data were accumulated in the Extracorporeal Life Support Organization Registry, an international registry for extracorporeal life support in pediatric patients. Although these data are useful, they are somewhat misleading, because their "survival rate" of 43% represents all patients who were weaned from the ECMO system. The survival to hospital discharge is not known, but judging from reports from other centers, it is almost certainly lower than the wean rate. In spite of the improved recent results of ECMO, it is unlikely that survival rates of patients having ECMO for cardiac failure will ever equal those of patients undergoing ECMO for respiratory support. Current limitations to survival include the complexity of the heart defects necessitating ECMO, the need for continued heparinization to prevent clotting in the ECMO circuit, and the higher incidence of infection related to the surgical implantation of the system.

Table 1. Extracorporeal Membrane Oxygenation for Postoperative Cardiac Failure

Center	No. of Patients	Weaned	Survived	% Survival
St. Louis University (Cardinal Glennon Hospital) (1982-1991)	65	44	23	35%

^b Incomplete data.

Several controversies continue over how to best apply ECMO support. The sites of cannulation differ among ECMO centers. Some centers use right atrial-aortic cannulation placed through the reopened sternotomy wound, whereas others have used the neck vessels [18]. The advantage of neck cannulation is the omission of the need to reopen the sternotomy wound, perhaps lessening the risk of bleeding from the surgical wound and the risk of mediastinitis. On the other hand, we have been concerned that carotid artery ligation would increase the risk of neurological injury, which is already high in these desperately ill patients. At least some of the patients undergoing neck cannulation have had the neck vessels repaired at the time of ECMO removal [18]. Femoral and iliac cannulations have also been used, but are not commonly used today. It seems clear from our clinical experience at Cardinal Glennon Children's Hospital that left heart cannulation may be required in some patients, because arteriovenous ECMO does not provide adequate decompression of the left ventricle [19-21] in patients with failing hearts, and actually increases left ventricular afterload [19, 20]. Left ventricular decompression can be accomplished with a relatively small left ventricular cannula [21]. Although left atrial cannulation may not provide complete left ventricular decompression, we have found it to be effective in most patients requiring postoperative ECMO. Whether left atrial or left ventricular cannulation is employed, it seems clear that some ECMO patients will require left heart support.

Ventricular Assist Devices

Ventricular assist devices (VADs) have been available in a limited way for children since the late 1970s. We employed a centrifugal VAD (Medtronic Corporation) in 4 children at Cardinal Glennon Children's Hospital during that period, with no survivors [22]. The causes of death in these 4 patients were primarily progressive right ventricular failure. These experiences prompted us to employ the ECMO system in children because it would provide better biventricular support. However, recent experience with VADs in postcardiotomy children have been more encouraging. Karl and associates [23] reported a 50% survival rate in infants and children with postcardiotomy heart failure supported with a left atrial-aortic centrifugal pump (Biomedicus-Medtronic, Minneapolis, MN). Nine of their patients required the assist device to be weaned from cardiopulmonary bypass in the operating room. Apparently, in their experience, the incidence of severe right ventricular failure with left VAD support was minimal. Furthermore, Hanley and colleagues, at Children's Hospital in Boston, have also employed the Biomedicus-Medtronic centrifugal pump in 9 children with severe heart failure after cardiac operations. In almost all patients they employed left atrial-aortic bypass, and 5 of their 9 patients survived. Several aspects of these studies are interesting and contrary to the more established experience with VAD support of postoperative heart failure in adults. Virtually all the children in these two series were supported with left heart support only, and right ventric-

ular failure was apparently not a common problem. This may have been because left VAD flows were kept at a lower rate to not overload the right ventricle. The other surprising finding is that 4 patients in Karl and associates' experience required dialysis during VAD support, and 2 of them were long-term survivors. In our experience with adult VAD support, there were no survivors among patients requiring dialysis during VAD support [24]. Table 2 lists the complications encountered in postcardiotomy VAD survivors and nonsurvivors (age < 18 years). Biventricular failure was the only complication that significantly affected survival.

The other area in which VADs have been useful in the pediatric population is in association with cardiac transplantation. Although bridging to transplantation has been quite successful in adults [25], it has been more difficult in children. Successful bridging has been accomplished in some instances. For example, at the University of Pittsburgh, 7 children have been successfully bridged to cardiac transplantation using an ECMO system, and 5 of them have actually survived transplantation (Del Nido PJ; personal communication, Oct 1991). Likewise, the use of circulatory support has been employed in the postoperative period after cardiac transplantation with some survivors [26]. In our own experience at St. Louis University, we employed ECMO in 6 patients after cardiac transplantation, with 2 survivors. Our first survivor lived 7 years but died after his second transplantation. A 1-year-old girl with severe biventricular failure is well 2 years after transplantation.

The primary limitation to the use of these devices for bridging to transplantation has been the miniaturization of the more sophisticated systems. However, at least two centers report the use of more sophisticated devices in children. The Berlin heart has been used successfully in children (Hetzer R; personal communication, Nov 1991), and the Japanese experience includes several children who were successfully supported with assist devices [27]. Bridge to transplantation data from the ASAIO-ISHLT Registry are shown in Tables 3 and 4. There were no significant differences in the percentages of survivors versus nonsurvivors in any of the postoperative complications. The survival rate after transplantation of 71% is comparable with that of adults [25].

It is apparent that miniaturization of the more sophisticated assist devices in the United States is imperative in order that the pediatric population be served, as well as adults. Devices to support infants with hypoplastic left heart syndrome might make more cases of transplantation possible. The advantages of several weeks of VAD support in heart failure patients are the ability to reverse organ dysfunction, eliminate edema, improve nutrition, and promote muscle gain. All of these features lead to a better result after transplantation. However, to provide these benefits, the devices must allow for ambulation and active exercise, which cannot currently be accomplished with ECMO and centrifugal VADs. It is now anticipated that the present decade will see the implantation of a permanent, totally implantable electrical left ventricular assist system in patients with chronic severe cardiac failure. Perhaps a totally implantable biventricular replacement device (total artificial heart) will follow within a few years. However, these devices are being designed for adults, so that the time when such devices might be made available to children and infants is not known. Some very preliminary work is being done [28], but currently seems far away from clinical trials. It is clear that cardiac trans-

plantation cannot provide enough donor hearts to satisfy the need for cardiac support in the younger population. Therefore, work must progress toward the development of more sophisticated temporary and permanent devices for infants and children.

Circulatory Support With Shock Due to Acute Myocardial Infarction

Anton Moritz, MD, and Ernst Wolner, MD

Second Surgical Department, University of Vienna, Vienna, Austria

Cardiogenic shock after acute myocardial infarction develops according to the amount of lost myocardium, function of remote myocardium, and the phenomenon of infarct expansion. Patients treated with mechanical support alone, without additional measures, have a mortality rate of 80%, the same as patients treated medically. Emergency angioplasty and emergency coronary artery bypass grafting can reduce mortality in certain subsets of patients to 40%. Patients with more severe shock and secondary organ dysfunction may be treated with me-

chanical bridging to transplantation with survival rates varying between 45% and 76%. Percutaneous support systems may be used to resuscitate a patient or to temporize, allowing time to perform diagnostic studies to determine if the patient is suitable for revascularization or heart transplantation. Intravenous enoximone may improve cardiac function as well and thus allow better decision making for further therapy.

(Ann Thorac Surg 1993;55:238-44)

Patients in whom cardiogenic shock develops after acute myocardial infarction have a very high in-hospital death rate. This dismal prognosis can be only slightly improved by intensive treatment in coronary care units using hemodynamic monitoring, fluid substitution, and inotropic agents. Mechanical circulatory support with the intraaortic balloon pump improves the hemodynamic condition but not the ultimate outcome [1]. Most patients in cardiogenic shock after acute myocardial infarction have lost 40% or more of their myocardium, either acutely or in combination with earlier infarcts [2]. Despite this fact the death rate is not strictly correlated to the mass of necrotic myocardium [3], but also depends on the functional state of remote myocardium [4]. As the amount of myocardium temporarily nonfunctioning is not known in the acute clinical setting, it is difficult to decide which patient will benefit from any type of revascularization. Another option for patients who are transplant candidates is to use mechanical blood pump support to bridge the waiting period until a suitable donor organ is available.

Patient Selection

There are several reasons why left ventricular power failure develops in patients with acute myocardial infarction. If the absolute amount of myocardium lost during the acute event or the addition of old and new infarctions adds to more than 40%, development of shock is highly probable [2, 5]. In addition, patients dying of cardiogenic shock showed marginal extension of the recent infarct and focal areas of necrosis throughout both ventricles in retrospective pathological studies [2].

Infarcted regions may undergo expansion by stretching of myofibrils during the first days. This increase in ventricular volume is correlated with hemodynamic deterioration and is the substrate for left ventricular aneurysm formation [6-8]. Reperfusion appears to limit this phenomenon by development of contraction band necroses, myocardial stiffening, and enhanced reparative processes [9, 10]. The development of myocardial infarction is often evolutionary, and infarcts of different age and signs of infarct extension at the margins of vital tissue are observed [2, 7].

The function of remote, noninfarcted myocardium determines the degree of compensation for lost contractile force. In general the stress produced by infarction causes deterioration of the metabolic condition of the entire heart [11, 12]. The amount of hypercontractility is inversely related to infarct size [4, 13-15]. In addition, blood flow to viable tissue supported by a stenotic noninfarct-related vessel may be severely impaired by occlusion of the culprit vessel [16, 17].

As the functional and pathologic changes leading to ventricular power failure are so complex, there must be several therapeutic strategies adapted to the individual circumstances of the patient. Successful percutaneous angioplasty of the infarct-related vessel within 12 hours of the onset of chest pain reduced the in-hospital mortality rate from 60% to 19% in hypotensive patients [18] and from 82% to 33% for patients in cardiogenic shock [19]. Mortality for emergency coronary artery bypass grafting within 18 hours after onset of cardiogenic shock was 7% when protection of the remote myocardium was accomplished with blood cardioplegia [20]. Survival for patients undergoing bypass grafting for shock is reported to be between 66% and 80% [20, 21].

Cardiogenic shock was defined differently in these studies, so the hemodynamic condition of the patients cannot be compared. Mechanical assistance with intraor-

tic balloon pumps or ventricular assist devices improved heart failure, but in-hospital mortality rate remained at 80% to 90% [1] (Table 1). A decision therefore must be made as to whether the patient should undergo any form of revascularization or should be considered a transplant candidate. To buy time to perform the necessary diagnostic studies, Loisance and associates [25] use a pharmacological bridge concept. In 7 of 10 patients in massive cardiogenic shock after acute myocardial infarction the hemodynamic situation improved after administration of a 1.5 to 2 mg/kg bolus of enoximone. A mechanical device had to be implanted on an emergency basis in only 3 patients [26]. Percutaneous assist devices are also able to stabilize patients for further diagnostic studies. Patients not considered transplant candidates may be offered revascularization techniques as an alternative even at high risk or, in the future, may be candidates for totally implantable assist devices.

Percutaneous Devices

There are several options for circulatory support by a quick, percutaneous approach. This avoids the need for a thoracotomy for installation and can be done in the catheterization laboratory. This method can be used to resuscitate patients, to perform diagnostic studies or angioplasty, or to buy time until more definitive measures can be taken. In addition there is experimental evidence that ventricular unloading can significantly reduce infarct size [27]. Reduction in infarct size was related to the degree of pressure unloading of the left ventricle, which is usually only achieved by direct ventricular cannulation [28, 29]. Adding counterpulsation to a percutaneous extracorporeal membrane oxygenation circuit was similarly effective in reducing myocardial necrosis [30, 31].

Mobile extracorporeal circuits mounted on a cart have been made commercially available. In the case of hemodynamic deterioration or during resuscitation one arterial and two venous cannulas are inserted into the femoral vessels using a Seldinger technique. Circulation can be reestablished by this technique as reported by Phillips [32] and Pennington and associates [33, 34], and survival rates are about 20% after subsequent treatment with angioplasty, bypass grafting, or heart transplantation.

The Nimbus Hemopump (Nimbus Medical Inc, Rancho Cordova, CA) can be inserted through a vascular graft sewn to the iliac or femoral vessels under fluoroscopic

guidance. It consists of a high-speed rotary pump contained in a perfusion cannula inserted across the aortic valve into the left ventricle. The system is powered and flushed through an axial cable. Insertion can be accomplished within 20 minutes and flow rates up to 3 to 3.5 L/min can be achieved. It definitely adds more circulatory support than does the intraaortic balloon pump, and it is possible to maintain circulation during ventricular fibrillation after sufficient fluid loading [35]. Coronary perfusion is improved, as shown in an experimental model [36]. On the other hand, unloading of a failing left ventricle may diminish its output, with blood flow achieved only by the Hemopump. As its flow maximum is limited, reversal of shock or recovery of organ function is often not achieved. Therefore most successful applications are reported when only short-term support was necessary [37, 38]. Deeb and associates [38] reported 3 surviving patients after successful implantation in 5 patients with acute myocardial infarction. In 3 patients the device could not be inserted due to technical reasons (Table 2).

Dennis and colleagues [39] designed a specially curved cannula containing an aspiration needle and a retractable knife to perforate the interatrial septum and thus to install left heart bypass. Lefemine and Dunbar [40] used percutaneous biventricular bypass with left ventricular and right atrial withdrawal, without the use of an oxygenator. For both methods only limited clinical experience is reported.

Bridging to Transplantation After Acute Myocardial Infarction

Since the first report of a successful bridge to cardiac transplantation for acute myocardial infarction shock [41], the combined registry of the International Society for Heart Transplantation and the American Society for Artificial Internal Organs (ISHT-ASAIO) lists a total of 262 patients treated with mechanical blood pumps to stabilize hemodynamics for cardiogenic shock complicating acute myocardial infarction. The devices used were total artificial hearts and pulsatile and centrifugal ventricular assist devices for either left, right, or biventricular support. Sixty-three of the 262 (24%) survived to hospital discharge. However, the treatment modalities of these patients were quite different. Seventy-nine patients were treated without the intention for later heart transplantation. Twenty-eight percent could be weaned from the

PCPB = percutaneous cardiopulmonary bypass system.

device, and only 10% were discharged from the hospital. Of the 76 patients who had an artificial blood pump implanted for later heart transplantation, 46 (60.5%) underwent transplantation and 34 (44.7%) could be discharged. Seventy-four percent of transplanted patients were discharged, indicating that mortality after the bridge period is somewhat higher than after conventional heart transplantation in mortally ill patients [42]. For the whole series there was no difference in the survival after support with centrifugal or pneumatic blood pumps. The survival for patients who had a total artificial heart implanted was 15 of 42 (36%). Though not clearly indicated, probably all of them were implanted with the intention of later heart transplantation. Farrar and associates [43] reported 17 patients receiving the Thoratec ventricular assist device system for acute myocardial infarction shock. Thirteen of these underwent transplantation and all of them survived to hospital discharge (76%). This is better than the reported 63% survival rate for the whole series including cardiomyopathies, transplant rejections, and myocarditis and the data for the combined registry (Table 3). This is consistent with the experience that survival rates after the use of ventricular assist devices tend to be better than those after use of total artificial hearts in bridged patients [43, 45-47]. Total artificial hearts have been used mostly before ventricular assist systems became easily available for clinical use, so the better results achieved with assist systems can be explained by the gain in experience. Kormos and associates [45] preferred the use of a total artificial heart over the use of an apicoaortic implantable left ventricular assist device (Novacor, Baxter Healthcare, Oakland, CA) due to the risk of ventricular arrhythmias and dislodgement of the apical cannula. This lethal complication was observed by Lewis and colleagues [26] after implantation of the TCI implantable left ventricular assist device (Thermo Cardiosystems Inc, Woburn, MA) in a patient with acute infarction.

Difficulties arise when one reviews the literature for mechanical circulatory support after acute myocardial infarction as some of the patients are operated on for infarct complications. So it is not clear whether these patients should be considered to receive implants for postcardiotomy shock or acute myocardial infarction shock. Survival for postoperative mechanical assistance is 24% (107 of 451 implants) [48] as reported by the ISHT-

ASAIO combined registry, although survival rates up to 40% may be achieved in experienced centers [49, 50]. Certainly timely implantation of the support device avoiding multiple attempts to wean the patient off extracorporeal circulation is a predictor for outcome [51], and the intention to implant a support device should be part of the surgical strategy in patients with preoperative shock. Noda and colleagues [22] reported a 38% survival rate for patients operated on for shock complicating acute myocardial infarction, whereas Pennington and associates [52] reported a dismal prognosis for patients with perioperative infarction requiring mechanical assistance. Still, in their series perioperative infarction did not preclude myocardial recovery and subsequent weaning from the assist device. The survival rate for patients with mechanical support after operation for acute myocardial infarction shock is reported to be 20% in the combined registry (Table 4).

Our Results

Six patients with cardiogenic shock complicating acute myocardial infarction were transferred to the Second Surgical Department of the University of Vienna for mechanical circulatory assistance as a bridge to heart transplantation.

The Vienna Heart was designed and is manufactured in cooperation between the Second Surgical Department and the Institute for Biomedical Engineering of the University of Vienna and the Ludwig Boltzmann Institute for Cardiosurgical Research in Vienna. A 65-mL ventricle is vacuum-formed from sheets of thermoplastic polyurethane (Pellethane). The two-layer pump membrane is solution-casted; the second layer also lines the inner surface of the pump housing, guaranteeing a seamless transition between housing and membrane. Flow is directed by a 29-mm (inflow) and a 27-mm (outflow) tilting-disk valve (Sorin, Italy). A 51F Sarns lighthouse cannula, bent to 90 degrees and coated with Pellethane, is used as inflow and a 12-mm expanded polytetrafluoroethylene graft is glued to the outflow cannula (Fig 1). Left heart bypass was always instituted between the right upper pulmonary vein and the ascending aorta. The ventricles are powered by a pneumatic drive unit [53]. Membrane position and motion was estimated by analysis of drive-line pressure and gas flow.

All patients were transferred in a state of cardiogenic shock (Table 5). They had been treated in coronary care units for several days after first or recurrent (patients 2, 4,

and 5) acute myocardial infarction. Four had renal failure, 1 of them treated with hemofiltration; 2 had impaired liver function with disorder of the coagulation system. A 65-year-old man had signs of adult respiratory distress syndrome indicated by roentgenogram and blood gas analysis after experiencing a large anterior infarction and cardiogenic shock. He underwent successful transplantation after 5 days of circulatory support (Fig 2). None of the patients had undergone coronary angiography due to their unstable hemodynamic condition. In all patients except patient 1, in whom no adequate pump flow could be achieved, the hemodynamic situation improved and organ function recovered. Recurrent ventricular fibrillation developed in 4 patients while they were supported by left ventricular assist. In 2 patients (patients 5 and 6) prolonged attacks of ventricular fibrillation led to multiorgan failure and neurologic deficit, respectively. Both had recovered initially, and the arrhythmia must be considered the main reason for the fatal outcome. Patient 4 improved hemodynamically and could be extubated 3 days after left ventricular assist device implantation. Urine flow had normalized, although serum creatinine level remained elevated. Severe graft failure developed on the first day after transplantation, with metabolic acidosis lowering pH to 6.9. Despite recovery of cardiac function

Fig 2. The chest roentgenogram of patient 3 shows signs of adult respiratory distress syndrome the first day after left ventricular assist device implantation, despite normal to low left atrial pressures.

he died of multiorgan failure acquired during this period of hypoperfusion.

Patient 2 had an elevated white blood cell count of $40 \times 10^9/L$ ($40,000/\mu L$) but no proven infection other than severe stomatitis. His renal failure necessitated hemofiltration before left ventricular assist device implantation. On the first postoperative day 17 L of fluid was necessary to stabilize his hemodynamics. In the later course multiple blood cultures were positive for *Klebsiella*, enterococci, and *Candida*. Under antibiotic treatment his organ functions stabilized, and as the implanted left ventricular assist device or the left ventricular thrombus was considered the septic focus, he underwent successful transplan-

Table 5. Characteristics of the 6 Patients Treated With Left Ventricular Assist Device Support With the Intent of Later Heart Transplantation at Our Institution

Patient No.	Age (y)	Creatinine (mg/dL)	Diureses	Bilirubin (mg/dL)	Lungs	Tx	Survival	Complications

tation after 22 days of support. All consecutive blood cultures were negative and he is alive and well 2 years later.

Comment

Decision making in the situation of cardiogenic shock complicating acute myocardial infarction is complex as optimal treatment depends on diagnostic information frequently not available in the acute setting. In addition to the amount of myocardium lost by the acute and earlier infarctions, the function of remote myocardium, infarct expansion, and infarct extension lead to left ventricular power failure. This range of causes explains why a variety of treatment modalities are reported to be successful in treatment of cardiogenic shock. The results of studies using different therapies are difficult to compare as the definition of cardiogenic shock varies and patients are treated at different times from onset of chest pain or cardiac failure.

Mechanical assistance using intraaortic balloon pumps or mechanical blood pumps was able to relieve cardiogenic shock, but in-hospital mortality and 1-year mortality were not improved significantly compared with medical treatment alone, ranging between 71% and 90% [1, 54] (see Table 1).

Restoring adequate blood flow to the myocardium may limit infarct size [55], avoid infarct expansion [10], or improve the function of remote myocardium [4]. Once cardiogenic shock is established it is usually too late to salvage myocardium in the infarct area. Despite this, angioplasty done within 12 hours of onset of pain improved survival in shock patients from 18% to 67% [19]. It is worth noting that mortality rates for patients with unsuccessful angioplasties parallel those of medically treated patients. Successful relief of cardiogenic shock is reported in 94% when surgical revascularization of the infarcted, as well as remote myocardium is done within a mean of 3.4 days after infarction [20]. In this study cardiac index was 2.1 L/m^2 and pulmonary capillary wedge pressure was increased to 27 mm Hg preoperatively. In-hospital mortality for the whole series was 18% and 1-year survival was 70%. Most of the late deaths were due to congestive heart failure. Patients operated on later than 18 hours after onset of shock had the worst short-term and long-term prognosis. In a review of 101 patients who underwent emergency coronary artery bypass presented by Bolooki [21], perioperative mortality was 66%.

Farrar and associates [43] reported a favorable outcome in patients with cardiogenic shock due to severe acute myocardial infarction (cardiac index, 1.6 L/m^2 ; pulmonary capillary wedge pressure, 27 mm Hg) after mechanical bridging to transplantation. Thirteen of 17 patients could undergo transplantation and were discharged from the hospital (76%). This survival rate is higher than that for their total series of 72 patients (63%) and the survival rate reported by the ISHT-ASAIO registry for this indication (45%). Although not generally achieved, these data indicate that even patients in severe shock can be managed with a very good outcome.

At this point there are no clear guidelines as to which devices are optimally used. Myocardial infarctions mostly affect left ventricular output, and so left ventricular assist is frequently sufficient to reestablish sufficient circulation. In all patients in our series we had to treat right ventricular failure with inotropes, but shock could be reversed in all but 1. Four of our patients had episodes of ventricular fibrillation while on the device, and in 2 of them these episodes were clearly related to death. Kormos and colleagues [45] thus suggest use of a total artificial heart preferentially in this setting. Biventricular assist is an adequate alternative as this overcomes problems of circulatory failure due to both arrhythmias and right ventricular failure, especially when the right coronary artery is diseased.

In contrast to patients with chronic cardiomyopathy, patients after acute myocardial infarction are not conditioned to hypoperfusion. Thus secondary end-organ dysfunction develops quickly and accounts for the increased mortality after coronary operation for shock [20]. The 2 survivors in our series had organ dysfunction that was considered in the literature to be a contraindication [56]. Still, reestablishing sufficient perfusion allowed for recovery of organ systems.

Percutaneous support was used to resuscitate patients in two series with a 20% survival after subsequent definitive treatment [32, 33, 38]. In addition, such devices may be used to temporize, allowing performance of diagnostic studies necessary to decide which treatment is optimal for the individual patient. In the state of evolving infarction, infarct size may be limited by these techniques as well [27, 31]. New inotropic drugs may be used as well to stabilize patients until the decision for final treatment can be made [44]. Patients with clear contraindications against heart transplantation, which cannot be expected to resolve during mechanical bridging, have the option to undergo revascularization procedures with increased risk or in the future to have one of the permanently implantable assist devices inserted.

Patients after acute myocardial infarction are seen in cardiogenic shock at variable intervals after onset of pain and with various reasons for ventricular failure. The value of different treatment strategies for these patients is not yet established, but revascularization techniques as well as mechanical assistance as a bridge to heart transplantation certainly significantly improve survival rates.

The Biopump and Postoperative Circulatory Support

George J. Magovern, Jr, MD

Department of Surgery, Allegheny General Hospital, Allegheny Campus, The Medical College of Pennsylvania, Pittsburgh, Pennsylvania

The Bio-Medicus Corporation, Inc, Minnetonka, MN, approached Allegheny General Hospital in 1978 for laboratory testing of a new pump to replace the standard roller pump [1], which had become associated with some of the damaging effects of cardiopulmonary bypass. Our initial attempts at using the Biopump for long-term assist were carried out by coating the Biopump, tubing, and connectors with a graphite-benzalkoniumchloride-heparin solution [2]. A dog was placed on left heart assist for a planned 6-hour study. Early in the experiment, we noted that the graphite material was peeling from the tubing and the Biopump. After 5 hours, the dog was in a state of disseminated intravascular coagulation and the experiment was terminated.

In a follow-up experiment, we used tridodecylmethyl ammoniumchloride to coat the tubing, connectors, and the Biopump. A dog was then prepared for left heart assist. However, when the Biopump was opened to prime the circuit, we noted that the solvent had weakened the strut supporting the concentric cones of the Biopump. Because the experiment had already been started, we decided to continue, but with an untreated Biopump, tubing, and connectors. The dog was placed on assist for 6 hours and survived the procedure. Importantly, coagulation studies were normal. Subsequent to this observation, 5 mongrel dogs were treated with left ventricle to femoral artery bypass using the Biopump for 24 hours at a flow ranging from 1.8 to 3.2 L/min. All animals survived the 24-hour left ventricular assist and recovered without sequelae.

From these and subsequent animal experiments, we made several interesting observations that contrasted to findings with the standard roller pump: (1) no inflow cannula obstruction and cavitation with resultant air embolization occurred, (2) serum hemoglobin levels in the experimental animals remained low, and (3) no anticoagulation was needed when the Biopump was run at 2,000 to 3,000 rpm for periods of up to 2 weeks.

Early Experimental Background

The rationale for use of the ventricular assist device (VAD) after an open heart operation is founded on the premise that reversible perioperative myocardial injury has oc-

curred. Reversibly injured postischemic heart muscle has been termed "stunned myocardium" by Braunwald and Kloner [3] and others. To study the recovery of stunned myocardium, our laboratory developed a model of normothermic ischemia to produce profound global myocardial dysfunction [4]. In the canine model, 45 minutes of global ischemia produced a severe myocardial injury, which was fatal with standard resuscitative techniques [5]. Our model was developed to determine whether such an injury would be reversible when treated with biventricular support using the Bio-Medicus pump.

Briefly, the heart was exposed through a midsternotomy incision and placed on biventricular support with cannulation of the femoral artery, left atrial appendage, right atrial appendage, and main pulmonary artery. The aorta was then cross-clamped for 45 minutes of normothermic ischemia, after which the cross-clamp was removed, resulting in immediate ventricular fibrillation. A beating, nonworking state was then maintained for the next 24 hours. During the initial hours after cross-clamp release, none of the hearts could sustain stable rhythm or blood pressure. After 12 hours of biventricular assist, an attempt was made to wean the dog from left and right ventricular assist by volume loading the heart. Measures of developed pressure and its first derivative (dp/dt) were obtained. At the end of 24 hours, a final attempt was made to wean the dog from the assist pumps. With complete ventricular decompression for 24 hours, developed pressure and dp/dt steadily improved. At 12 hours of assist, developed pressure had recovered to 66% of control, and after 24 hours of support, 7 of the 10 animals were successfully weaned from biventricular assist. Left ventricular function parameters were essentially normal in these animals, and a subsequent analysis of myocardial water content indicated no significant myocardial edema formation. Recovery of myocardial adenosine triphosphate level also closely paralleled the return of ventricular function. By 24 hours of reperfusion, myocardial adenosine triphosphate stores had fully recovered to control levels.

Finally, an analysis of myocardial ultrastructure was useful in that it provided further evidence that the 45-minute ischemic insult was severe but not irreversible. After 45 minutes of normothermic ischemia, there was moderate ultrastructural damage. After 24 hours of support, none of the tissues in any group showed severe myocardial injury with the disruption and flocculent

Presented at the Circulatory Support 1991 Symposium of The Society of Thoracic Surgeons, San Francisco, CA, Nov 16-17, 1991.

density formation of irreversible cell injury. Thus, a full 24 hours of ventricular assist was required for functional, metabolic, and structural recovery.

In a similar model from our laboratory, Demmy and associates [6] attempted to shorten the time for hemodynamic recovery of injured myocardium by administering adenosine-enriched cardioplegia at the end of 45 minutes of normothermic ischemia. Animals treated with adenosine after ischemia had a faster recovery of left ventricular function than did control animals. One hour after weaning from circulatory support, adenosine-treated animals had higher left ventricular peak pressure (110 ± 21 versus 57 ± 36 mm Hg), greater dP/dt ($3,407 \pm 812$ versus $1,510 \pm 1,376$ mm Hg/s), and lower left ventricular end-diastolic pressure (23.8 ± 4.8 versus 34.0 ± 7.2 mm Hg) than the control group. In addition, the recovery of adenosine triphosphate levels was significantly greater in the adenosine-treated group, which correlated nicely with the hemodynamic results. Thus, adenosine clearly accelerated left ventricular recovery and shortened the time required for biventricular assist after a uniform global ischemic injury. The mechanism postulated for this improvement is that adenosine is extracted from the coronary circulation and used to increase the level of intracellular adenosine nucleotides.

Centrifugal Ventricular Assist Protocol

Description of Device System

The ventricular assist device system used at Allegheny General Hospital consists of a commercially available centrifugal vortex pump (Biopump; Bio-Medicus, Inc, Minnetonka, MN) and standard cannulas and tubing found in routine cardiopulmonary surgery. The system can be used for partial circulatory assist or for total replacement of right and left ventricular function.

For left heart support, cannulation is achieved via the left atrium through either the atrial appendage or right superior pulmonary vein, with return via a cannula in the aorta. For biventricular assist, the right atrium is cannulated in standard fashion as for cardiopulmonary bypass, with return via the main pulmonary artery. The following equipment and supplies should be available: (1) Bio-Medicus pump console, (2) Bio-Medicus disposable pump head, (3) Bio-Medicus flow transducer, (4) Bio-Medicus disposable flow probe, (5) sterile 3/8-inch $\times$ 3/16-inch tubing (approximately 10 feet), (6) tubing clamps (four), (7) priming solution (typically 3 L of Plasmalyte A), (8) large sterile basin (5-L capacity), (9) battery pack, and (10) patient management data sheets.

Indication for Use

The Bio-Medicus pump is appropriate for use in several different clinical situations: patients unable to be weaned from cardiopulmonary bypass after a technically successful open heart operation and who are deemed to have potentially salvageable myocardium; patients in cardiogenic shock secondary to idiopathic cardiomyopathy or to acute myocardial infarction and who are candidates for

heart transplantation; patients with postoperative development of cardiogenic shock after a successful operation with potentially salvageable myocardium; and patients in cardiogenic shock after acute myocardial infarction who are not surgical candidates but who might have reversibly injured or stunned myocardium.

Contraindications

Contraindications include active systemic infection, chronic debilitating diseases, neurologic impairment, metastatic cancer, no potentially salvageable myocardium, blood dyscrasia, or any problem obviating heart transplantation.

Cannulation for Left Ventricular Assist

The left atrial cannula (usually 32F or 34F Sarns venous cannula) can be placed through either the left atrial appendage, the right superior pulmonary vein, or the roof of the left atrium.

Typically, the heart is retracted to expose the left atrial appendage or the right superior pulmonary vein. Purse-string sutures with Teflon pledgets are placed in the base of the appendage, or in the right superior pulmonary vein, and passed through rubber tourniquets. The left atrial pressure is raised by restricting the venous return, the atrium is opened, and the cannula is inserted. After the left atrial cannula is secured, it is connected to the inflow line of the Biopump. All air must be excluded from the connection and tubing at this time. The aortic cannula previously placed for cardiopulmonary bypass will be switched to the outflow line from the Biopump at the appropriate time.

Initiation of Left Ventricular Assist

Cardiopulmonary bypass flow is reduced gradually while the left atrial pressure is monitored by either a left atrial line or pulmonary artery wedge pressure. When the left atrial pressure reaches 20 mm Hg, assist flow is initiated. Cardiopulmonary bypass flow is then discontinued, and the venous line is clamped. The aortic arch cannula is clamped and the cardiopulmonary bypass perfusion line quickly removed. The Biopump outlet line is then connected to the arch cannula. All air must be excluded from the connection and tubing at this time. Assist flow is initiated and increased incrementally. The total systemic blood flow (native ventricular output + ventricular assist pump flow) is maintained at $2.2 \text{ L} \cdot \text{min}^{-1} \cdot \text{m}^{-2}$. Left atrial pressure or pulmonary artery wedge pressure is maintained in the 5 to 15 mm Hg range by volume adjustment.

Most patients will have some degree of right heart failure when the left ventricular assist is initiated. If left ventricular assist pumping cannot maintain a $2.2 \text{ L} \cdot \text{min}^{-1} \cdot \text{m}^{-2}$ cardiac index with good cannula placement and adequate volume, then right heart failure is present and right heart assist may also be required.

Preparation and priming of the Biopump is completed as previously described. The right atrial cannula placed for cardiopulmonary bypass is connected to the inflow

line of the second Biopump. A pulmonary artery catheter (typically, 22F Bard right-angle aortic arch cannula) is inserted into the pulmonary artery distal to the pulmonic valve and secured with pursestring sutures. Cannulas are brought out through the superior or inferior aspect of the incision. The skin is approximated, whereas the sternum is not. The perfusion lines are securely sutured to the skin and covered with several towels and a large adhesive plastic drape.

When a patient is on biventricular assist, coordination of the left and right flow rates requires manipulation of the pumps sequentially with close monitoring of the pulmonary artery pressure. The right assist pump flow is gradually increased while the left pump flow is incrementally raised to accommodate the right-sided output. The right assist pump must unload the right ventricle efficiently for the left assist to pump a minimum of $2.2 \text{ L} \cdot \text{min}^{-1} \cdot \text{m}^{-2}$. Left atrial pressure should be 5 to 15 mm Hg.

Anticoagulation Regimen and Coagulopathy

After cardiopulmonary bypass, heparin should be reversed with protamine. After returning to the intensive care unit, the patient is not anticoagulated until clotting studies have normalized, after which administration of heparin is started to maintain activated clotting times greater than 150 seconds. The perfusionist on duty is responsible for performing activated clotting time monitoring and determining necessary heparin doses.

Weaning of Ventricular Assist

Weaning is usually not attempted during the first 24 hours of assist support. When the clinical picture is stable and cardiac recovery is suspected, a weaning assessment can be completed in 3 minutes or less. Assessment parameters are documented by the perfusionist on duty as follows. Pump flow is never decreased to less than 1 L/min. At 1 L/min, the activated clotting time must be greater than 180 seconds, and the duration of time at this flow must not exceed 2 minutes. If the pump flow is to be kept at 1 L/min for longer than 2 minutes, the activated clotting time must be extended to 200 seconds. Biventricular assist devices may be weaned concomitantly in the same manner as single VADs or separately in a stepwise manner.

ASSESSMENT PROCEDURE. For the left ventricular assist device, decrease assist pump flow rate to a rate that induces an increase in left atrial or pulmonary artery wedge pressure to 20 to 25 mm Hg. At the same time, record arterial pressure wave form and monitor for signs of left ventricular ejection. For the right ventricular assist device, decrease assist pump flow to a rate that induces an increase in right atrial pressure to 20 to 25 mm Hg. Concomitantly, record the pulmonary artery pressure in waveform and monitor for signs of right ventricular ejection.

If, after 1 minute of reduced flow, no native ventricular ejection is evident, the assist pump flow is returned to

previous levels. *The combined flow of the native ventricle and the assist pump should always deliver a minimum cardiac index of $2.2 \text{ L} \cdot \text{min}^{-1} \cdot \text{m}^{-2}$.*

If ventricular ejection is noted during weaning, calculate cardiac output by both thermodilution and Fick methods. If substantial recovery is noted, order transesophageal echocardiography as a STAT procedure and return the patient to full VAD support. The staff should perform the transesophageal echocardiography at bedside with the assist pump at 1 L/min flow.

Staged weaning is guided by the degree of cardiac recovery as documented by cardiac output and transesophageal echocardiographic results. When the surgeon determines that the native ventricle can support the required cardiac output, remove the assist cannulas in the surgical intensive care unit or operating room under strict aseptic technique.

Clinical Results

From June 1980 to July 1991, 15,500 patients underwent cardiopulmonary bypass support for cardiac operations at Allegheny General Hospital. Refractory cardiac failure requiring extended support with a centrifugal VAD developed in 77 (0.5%) of these patients. Of the 77 patients, 37 received a left VAD, 4 a right VAD, and 36 a bi-VAD. There were 52 men and 25 women whose ages ranged from 34 years to 74 years, with an average of 56.5 years.

The primary surgical procedures consisted of 52 coronary revascularization procedures, 8 valve replacement operations, 9 combined valve-coronary procedures, 3 combined coronary left ventricular aneurysmectomy procedures, 2 left ventricular aneurysm resections alone, and 3 miscellaneous cases. Nine patients had undergone previous cardiac operations. All patients were protected with cold cardioplegic solution, topical Ringer's slush, and systemic hypothermia. Concomitant intraaortic balloon pumping and pharmacologic support were implemented in all cases. The median sternotomy incision was either left open and packed or sealed with an Esmarck patch. Pump flow rate, which is critically dependent on preload, was manipulated to maintain a cardiac index of $2.2 \text{ L} \cdot \text{min}^{-1} \cdot \text{m}^{-2}$ or greater. High flows were maintained, not only to unload and rest the ventricle, but to minimize or eliminate the need for heparin. Flows of less than 2 L/min were only allowed intermittently for assessment of ventricular recovery. Activated clotting times were managed between 150 and 200 seconds. The assist device was implanted in 65 patients immediately after the initial operation and in 12 patients who suffered subsequent hemodynamic deterioration 2 to 48 hours after operation.

Overall duration of assist ranged from 6.5 to 184 hours, with a mean of 52 hours. Average length of assist for left VAD, right VAD, and bi-VAD was 45, 49, and 60 hours, respectively.

Of the 77 patients, 34 (44%) died on the device (non-survivors), 16 (21%) were weaned but died before discharge (short-term survivors), and 27 (35%) were dis-

charged (long-term survivors). Length of assist was not significantly different among the three groups. Long-term survivors were equally distributed between left VADs and bi-VADs (34% versus 37%).

Cardiac failure and associated organ failure was the cause of death for all unweanable patients (nonsurvivors). Four short-term survivors died of sepsis, and 1 died of a ruptured infected femoral artery secondary to a prior intraaortic balloon pump insertion; the remaining deaths were due to progressive cardiac failure.

Postoperative bleeding (83%), which required frequent reexploration and multiple transfusions, was the primary complication of VAD support. Sepsis was the second most frequent complication, resulting in three deaths. Renal dysfunction (creatinine level >2.0 mg/dL) occurred in approximately 35% of all patients, but only 7 patients required dialysis while on support (1 long-term survivor, 5 short-term survivors, and 1 nonsurvivor). Permanent neurological deficits were documented in 6 patients (4 long-term survivors and 2 short-term survivors). The cause (embolic or ischemic) could only be determined in 1 early patient and was thought to be embolic because the event occurred shortly after weaning.

Survival was not significantly influenced by age, sex, primary procedure, aortic cross-clamp time, type of assist, length of assist, or the complications of VAD support. Survival increased significantly ($p < 0.05$) when analyzed by operative era. From 1980 through 1984, survival was 25% as compared with 45% for 1985 through April 1991. This improvement is attributed to increased physician and perfusionist expertise with the system, more aggressive institution of assist support, and better patient selection.

Of the 27 long-term survivors, 17 are alive and 10 are dead. The length of hospital stay for long-term survivors ranged from 15 to 199 days after weaning. The follow-up period after hospital discharge ranged from 0.14 to 10.8 years with a mean of 4.0 years. Observation time for the 17 alive patients in follow-up ranges from 0.4 to 10.8 years, with a mean of 5.4 years. Cumulative 5-year survival for all discharged survivors is 59%.

Six long-term survivors died within 1 year after weaning. Before death, all 6 patients were in New York Heart Association (NYHA) class III. Four patients in NYHA class III died late at 3.1, 3.3, 3.4, and 4.5 years. Cardiac failure was responsible for nine deaths, whereas respiratory failure and pneumonia accounted for the remaining death.

Before operation, 13 of the 17 alive patients were in NYHA class IV, 2 were in class III, and 2 were in class II. Three NYHA class IV patients were in cardiogenic shock, 1 from acute MI and 2 from acute failed percutaneous transluminal coronary angioplasties. Of the latter 3 patients, 2 are in NYHA class II and 1 is in NYHA class I in follow-up. At follow-up, 14 patients are in NYHA class I, 2 are in class II, and 1 is in class III. Ten patients have returned to full working and recreational lifestyles. Four NYHA class I patients are disabled due to noncardiac postoperative sequelae.

Interestingly, 1 long-term survivor returned 2 years after VAD support, underwent uneventful reoperative

coronary artery bypass grafting, and is surviving in NYHA class I with no limitations.

A substantial number of patients with postcardiotomy ventricular failure have reversible injuries as demonstrated by our overall salvage rate of 35% (27/77), our long-term (>3 years) survival rate of 67% (18/27), and our 59% cumulative survival at 5 years for discharged long-term survivors. After 10 years of clinical experience with a centrifugal VAD, we have not yet discovered specific variables that predict recovery in a majority of VAD patients. Our experience also supports the long-term efficacy of VAD support for postcardiotomy patients.

Survivors can reasonably expect to have an excellent quality of life. We, therefore, advocate a continued focused effort on the development of more effective VADs for application in patients after open heart operations.

Future Directions

The Allegheny General Hospital ventricular assist program continues to evolve. Most recently, we have used the Medtronic/Carmeda (Minneapolis, MN/Stockholm, Sweden) extracorporeal membrane oxygenator system in 4 postcardiotomy patients. This system essentially consists of a heparin-coated fiber oxygenator, a disposable Biopump, sterile tubing, and various heparin-coated cannulas for the femoral artery or aortic arch, and for the femoral vein or right atrium.

In one of the more promising recent breakthroughs in the field of biocompatible materials, Olle Larm, chief chemist at Carmeda, successfully developed a technique to bond heparin covalently to foreign surfaces [7]. Larm noted that the heparin molecule has an active component that must be freely exposed to the blood if the chemical chain reactions that prevent coagulation are to take place. Heparin must stand up from the surface as a result of a covalent binding process known as end-point attachment.

Heparin is a naturally occurring polysaccharide, the anticoagulant effect of which occurs primarily through its activation of the enzyme antithrombin. Antithrombin then inactivates thrombin, the enzyme needed in the final pathway for clot formation. The covalent bond developed by Carmeda is situated at the terminal aldehyde group of heparin, allowing the antithrombin binding sites to remain free. Importantly, the process is nonleaching while in contact with blood, saline solution, or albumin. The resulting surface is stable and thrombin-resistant.

The Allegheny General group has used the system in treating 4 patients, with no device failures. The system effectively decompresses both the left and right sides of the circulation. Cannulas have been inserted via the femoral artery-femoral vein approach, as well as through the aortic arch and right atrium. Insertion is not technically difficult. If the device is implanted through the chest, the midsternotomy incision is left open. The femoral approach allows for chest closure. Bleeding has not been a problem, and the oxygenator has been both reliable and effective for nearly 60 hours. The assist device has not required additional heparin, the flow rate has been at least 4 L/min, and the average assist time has been 41 hours.

Coagulation profiles including activated clotting time, platelet count, prothrombin times, partial thromboplastin times, fibrinogen levels, and fibrin split product levels have not demonstrated any damage to the blood elements. Importantly, there has been no problem with disseminated intravascular coagulation.

All 4 patients placed on the device after cardiectomy were successfully weaned from the device. Two of the 4 are considered to be long-term survivors. These 2 survivors both underwent coronary artery bypass grafting procedures for cardiogenic shock complicated by an acute myocardial infarction. A third patient was placed on the Carmeda system after mitral valve repair and concomitant coronary artery bypass grafting for severe ischemic mitral regurgitation. Although weaned from the device, the patient ultimately died of cardiac failure. A fourth patient had development of acute right heart failure after heart transplantation. The device was used as a bridge for 48 hours, at which time a second donor heart was procured. The patient ultimately died of right heart failure.

At this point, the clinical indications for using this device are not defined; however, the system appears to have promise in treating patients with postcardiotomy cardiogenic shock. In addition, it may have a role in treating patients suffering from cardiogenic shock after

acute myocardial infarction or cardiac or multisystem trauma.

Clinical Experience With Ventricular Assist Systems in Japan

Hisateru Takano, MD, PhD, Takeshi Nakatani, MD, PhD, and
Yoshiyuki Taenaka, MD, PhD

National Cardiovascular Center, Research Institute, Osaka, Japan

In Japan, five types of ventricular assist system, including the government-approved National Cardiovascular Center type and the Tokyo University type, were applied to 202 patients as of September 30, 1991. Adult-sized ventricular assist systems were used in 194 patients and a pediatric one in 8. The major primary diagnosis was ischemic heart disease (52.5%). Sixty-three patients in cardiogenic shock with acute myocardial infarction were treated using a ventricular assist system, and the results were fairly good. The predominant indication was failure to be weaned from cardiopulmonary bypass (72.8%), and there was no case of bridging to heart transplantation. Left ventricular assist was performed in most pa-

tients (85.1%). The duration of ventricular assist system application ranged from 1 hour to 70 days, and the mean duration was 6.8 ± 9.6 days. Duration of circulatory support had no relation to the results, and the longest support in survivors was 25 days. The weaning rate was 50.0%, and the survival rate was 26.2%. Main causes of death were heart failure, including unrecoverable heart failure, and multiple organ failure. It should be kept in mind that the decision to use a ventricular assist system should be made quickly, before major organs, including the heart itself, are irreversibly damaged.

(*Ann Thorac Surg* 1993;55:250-6)

The main purposes for temporary use of a ventricular assist system (VAS) are to maintain the normal circulation irrespective of the severity of heart failure and to restore the failing heart by gradually decreasing the bypass flow as the heart recovers [1, 2]. Research on and development of an artificial heart in Japan started in the late 1950s with the initial objective of cardiac replacement [3]. In the late 1970s, several groups continued to develop a VAS under the stimulus of some successful reports of clinical application from the United States [4-8]. After considerable accumulation of experimental experience, the first clinical application of a VAS in a postcardiotomy patient was performed in 1980 by the Tokyo University group, which was followed by a continuous expansion of clinical applications of VAS using several types of pulsatile blood pump [9, 10].

In response to the demand for availability of such a device, two types of VAS, the National Cardiovascular Center (NCVC) type and the Tokyo University type, were put into clinical evaluation for efficacy and safety under the guidance of the Japanese Ministry of Health and Welfare so as to obtain governmental approval for commercial release. Both types of VAS were approved by the Japanese government in January 1990, and became commercially available after successful results were obtained

in clinical trials conducted on more than 60 patients each [11-13]. In this report, clinical experiences with external pulsatile VASs in Japan are described.

Material and Methods

Description of the Ventricular Assist Systems

In the majority of patients, two types, the NCVC type and the Tokyo University type, were used. These two types had already obtained governmental approval as mentioned above. Two other types were used for some clinical cases, the Tohoku University type (pneumatic sac type) and the Thomas Giken type (pneumatic diaphragm type), although these have not yet been approved by the Japanese government. The Thoratec type (pneumatic sac type) also was used in the initial stage of clinical application.

NATIONAL CARDIOVASCULAR CENTER-TYPE VAS. The NCVC-type VAS was developed at the National Cardiovascular Center in Osaka and is manufactured presently by the Toyobo Co, Ltd, also located in Osaka [14, 15]. Two sizes (adult and pediatric) of blood pump are available; the paracorporeal, pneumatic, and diaphragm-type pumps are made of Toyobo TM series segmented polyether polyurethane (Fig 1). The pump body is fabricated without a seam. Two no. 23 Björk-Shiley valves and two no. 21 Björk-Shiley valves are used in the inlet and outlet ports of the adult-sized pumps and pediatric-sized ones, respectively. The effective stroke volumes are 70 and 20 mL, and the maximum outputs are 7.0 and 2.4 L/min, respectively. It has been proved in animal experiments that no antico-

B

Fig 1. The National Cardiovascular Center-type ventricular assist system: (A) pediatric (right) and adult (left)-sized blood pumps; (B) standard (left) and compact (right) control-drive units.

agulant is needed when the bypass flow is maintained at greater than 2.0 L/min in the adult-sized pump and 0.8 L/min in the pediatric one [14, 16]. The bypass flow was measured continuously by an electromagnetic flow probe fitted on an outlet conduit. There are two types of control-drive unit (CDU): the standard type with two regular and two backup drivers, and the compact one with one regular driver and one backup driver. The main part of the CDU consists of an automatic electrocardio-

gram synchronization system and an automatic bypass flow control system based on automatic level control of left atrial pressure and flow, in which bypass flow can be altered closely following changes in cardiac function [17]. Two types of CDU are shown in Figure 1. The latest versions of both types of CDU are applicable as the driver for intraaortic balloon pumping and permit 30 minutes of pumping by a built-in compressor and vacuum unit with internal batteries [18].

TOKYO UNIVERSITY-TYPE VAS. The Tokyo University-type VAS was developed at Tokyo University [19]. The blood pump is paracorporeal, pneumatic, and sac-type (Fig 2). The pump and cannulas are made of polyvinyl chloride, and all blood-contacting surfaces are coated with Carbiothane. Two no. 19 Björk-Shiley valves are used as inlet and outlet valves, and an electromagnetic flow probe is placed at the outflow conduit to measure pump output. The stroke volume is 40 mL, and the maximum flow is approximately 5 L/min. This pump is now produced by Nippon Zeon Co Ltd, Tokyo, Japan. The CDU is equipped with a compressor and vacuum pump that can drive two pumps at the same time (see Fig 2). It is capable of functioning in synchronous or asynchronous mode to the electrocardiogram or aortic pressure. Another feature of this CDU is that it has a back-up driver and internal battery packages, which permit 40 minutes of pumping. This CDU is manufactured by Aishin Seiki Co Ltd in Kariya, Aichi, Japan.

Criteria for Use or Removal of Ventricular Assist System

The hemodynamic criteria for profound heart failure are cardiac index less than $2.0 \text{ L} \cdot \text{min}^{-1} \cdot \text{m}^{-2}$ in adults and $2.3 \text{ L} \cdot \text{min}^{-1} \cdot \text{m}^{-2}$ in pediatric patients, systolic arterial pressure less than 80 mm Hg, left atrial pressure greater than 18 mm Hg for left ventricular failure, and a right atrial pressure greater than 18 mm Hg with a left atrial pressure less than 5 mm Hg for right ventricular failure. The subordinate criteria are urine output less than $0.5 \text{ mL} \cdot \text{kg}^{-1} \cdot \text{h}^{-1}$, mixed venous oxygen saturation less than 65%, and arteriovenous oxygen difference greater than 7.0 vol%. Clinical impressions are also important. When the circulatory condition stays within these criteria in spite of medical therapy and the use of intraaortic balloon pumping, a left ventricular assist system (LVAS) or a right ventricular assist system (RVAS), or both, was applied.

Criteria for removal of the VAS are a cardiac index greater than $2.5 \text{ L} \cdot \text{min}^{-1} \cdot \text{m}^{-2}$ in adults and $2.7 \text{ L} \cdot \text{min}^{-1} \cdot \text{m}^{-2}$ in pediatric patients, systolic arterial pressure greater than 100 mm Hg, mixed venous oxygen saturation greater than 65%, and left atrial pressure or right atrial pressure less than 18 mm Hg.

Surgical Techniques for the Implantation of the Ventricular Assist System

The blood pump was installed between the left atrium and the ascending aorta for the LVAS. Cannulation sites of the inlet conduit were the interatrial groove along the

Fig 2. The Tokyo University-type ventricular assist system: (A) blood pump with stroke volume of 40 mL; (B) control-drive unit.

right side of the heart, the left atrial appendage, or the right atrium through the atrial septum. For the RVAS, the blood pump was installed between the right atrium and

Table 1. Duration of Circulatory Support

Variable	No. of Patients	Duration	
		Range	Mean $\pm$ Standard Deviation (d)
Not weaned	101	1 h-70 d	6.7 $\pm$ 12.7
Weaned	101	1 h-25 d	6.8 $\pm$ 4.9
Did not survive	48	4 h-23 d	7.2 $\pm$ 4.9
Survived	53	1 h-25 d	6.4 $\pm$ 4.8
Total	202		6.8 $\pm$ 9.6

the main pulmonary artery. An atrial cuff was used for insertion of the inlet conduit in patients with the NCVC-type VAS.

Patient Profiles

The database of this report as of September 30, 1991, consisted of 202 patients treated with several types of VAS in 41 hospitals in Japan. These included 133 male patients (65.8%) and 69 female patients (34.2%), whose ages ranged from 9 months to 77 years (mean, 54.9 $\pm$ 16.9 years). Adult-sized VASs were applied to 194 patients, whose ages ranged from 13 years to 77 years, and a pediatric-sized one in 8, whose ages ranged from 9 months to 10 years. The indications for application of VAS were failure to be weaned from cardiopulmonary bypass in 147 patients (72.8%), postoperative low cardiac output syndrome in 44 patients (21.8%), and cardiogenic shock without surgical procedure in 11 patients (5.4%).

Results

Types of Device

Five types of device were used: 99 patients (49.0%) were treated with the NCVC-type VAS, 83 (41.1%) with the Tokyo University-type VAS, 14 (6.9%) with the Thomas Giken-type VAS, 3 (1.5%) with the Tohoku University-type VAS, and 3 (1.5%) with the Thoratec-type VAS.

Pump Size and Results

Adult-sized blood pumps were applied to 194 patients; 98 patients (50.5%) were weaned and 53 patients (27.3%) survived. Pediatric-sized blood pumps of the NCVC-type VAS were used in 8 patients; 3 of them (37.5%) were weaned, but none of them survived. The body weight of these patients was between 5.8 and 14 kg.

Duration of Circulatory Support

In the total series of 202 patients, 101 patients (50%) were successfully weaned from the VAS, and 53 patients (26.2%) were long-term survivors who were alive more than 1 month. The duration of circulatory assist had no relation to the results, as shown in Table 1.

Distribution by Year and Results

The first clinical application was performed in 1980 (Fig 3). Between 1986 and 1988, governmental clinical trials of the NCVC-type VAS and the Tokyo University-type VAS were performed and the number of trials reached 153.

Fig 3. Distribution by year and results (through Sep 30, 1991).

During these clinical trials, the blood pump set was provided free of charge. After the approval, the number of VAS cases decreased, because the cost of these two types of VAS was not covered by medical insurance.

Distribution by Age and Results

Ages of more than 85% of patients ranged from 40 to more than 70 years, whereas there were 7 children (3.5%) less than 10 years old (Fig 4). Thirty patients, or 14.9%, were more than 70 years old, and their results were better than those of the patients between 60 and 70 years old. The patients aged 40 to 50 years had the best clinical results. The mortality of young patients was high.

Primary Diagnoses and Results

Of 202 patients, primary diagnoses were ischemic heart disease in 106 (52.5%), valvular heart disease in 48 (23.8%), and ischemic heart disease with valvular heart disease in 11 (5.4%) (Fig 5). Other diagnoses included congenital heart disease in 19 (9.4%), aortic disease in 11 (5.4%), and miscellaneous diseases in 8 (4.0%). Clinical results in patients with congenital heart disease and aortic disease were worse, and no one survived in the latter group.

Indications for Ventricular Assist System Application and Results

The VAS was applied to 147 patients (72.8%) because they could not be weaned from cardiopulmonary bypass (Fig

Fig 4. Distribution by age and results (through Sep 30, 1991).

Fig 5. Primary diagnoses and results (through Sep 30, 1991). (IHD = ischemic heart disease; VHD = valvular heart disease.)

6). Forty-four patients required VAS application because of postoperative low cardiac output syndrome. Eleven patients received the VAS because of cardiogenic shock after no surgical procedure was performed. In postcardiotomy patients, the patients with failure to be weaned from cardiopulmonary bypass showed better results than those with postoperative low output syndrome. This may be related to earlier application of VAS in the former. In cardiogenic shock without a surgical procedure, 3 of 11 patients (27.3%) were weaned from the VAS and 2 patients (18.2%) survived.

No patients received a VAS as a bridge to heart transplantation because there is no consent to transplantation with a brain-dead donor in Japan.

Types of Assist and Results

An LVAS has been used for the majority of patients (172 patients; 85.1%) (Fig 7). Another 17 patients (8.4%) received an RVAS, and 13 (6.4%) a biventricular assist system. The results in patients with an RVAS were much better than those in patients with an LVAS. The rate of separation from RVAS and survival rate were excellent. The worst clinical results have been obtained in patients with biventricular assist, which corresponds to the experience in other countries.

Fig 7. Types of assist and results (through Sep 30, 1991). (BVAS = biventricular assist system; LVAS = left ventricular assist system; RVAS = right ventricular assist system.)

Assisted Duration and Results

The assisted duration of VAS and the corresponding clinical results for 202 patients are shown in Figure 8. The duration ranged from 1 hour to 70 days, and most patients were on the VAS for less than 14 days. Of the 59 patients on the VAS from 3 to 7 days, 46 (78.0%) were weaned and 27 (45.8%) survived. These results are fairly good. The longest support was 70 days, and the longest support in a patient who survived was 25 days. Of those receiving VAS support for less than 1 day, only 9 (18%) were weaned and 5 (10%) survived. The corresponding figures for patients receiving VAS support for more than 14 days were 8 (42.1%) and 3 (15.8%), respectively.

Acute Myocardial Infarction With Cardiogenic Shock

Sixty-three patients with cardiogenic shock after an acute myocardial infarction were treated with a VAS. An LVAS was applied to more than 95% of patients. Diagnoses and procedures are summarized in Table 2. In the group with acute myocardial infarction, 2 of 5 LVAS patients without coronary artery bypass grafting were weaned and 1 survived. In the group with acute myocardial infarction and ventricular septal perforation, the patients with LVAS application with ventricular septal perforation closure

Fig 8. Assisted duration and results (through Sep 30, 1991).

Table 2. Acute Myocardial Infarction With Cardiogenic Shock

Condition	Procedure	No. of Patients	Weaned	Survived
AMI	CABG	26	10 (38.5%)	6 (23.1%)
	No CABG	5	2 (40.0%)	1 (20.0%)
AMI + VSP	Closure	30	19 (63.3%)	9 (30.0%)
	No closure	1	0 (0%)	(0%)
AMI + MR	CABG + MVP	1	1 (100%)	1 (100%)
Total		63	32 (50.8%)	17 (27.0%)

AMI = acute myocardial infarction; CABG = coronary artery bypass grafting; MR = mitral regurgitation; MVP = mitral valve plication; VSP = ventricular septal perforation.

showed a better weaning rate (63.3%) and survival rate (30.0%).

Causes of Death

Major causes of death in nonweaned patients were heart failure, multiple organ failure, and bleeding (Fig 9). After removal of the VAS, they included multiorgan failure and recurrent heart failure.

Postoperative Findings in the Blood Pumps of NCVC Ventricular Assist Systems

Pictures of representative postoperative pumps of the NCVC-type VAS in its clinical trial with 92 patients are shown in Figure 10. In most cases, inside the pump was very clean (see Fig 10A). However, macroscopic ring-shaped thrombus formation was noticed in the groove around the valve (ring-shaped thrombus) in 8 patients in the clinical trial (8.7%) (see Fig 10D). Macroscopic thrombus formation was also noticed inside the pump in 8 (see Fig 10C). Concerning this type of thrombus formation, strong and repeated contact of the diaphragm with the housing might have caused delamination of the absorbed protein layer, resulting in the formation of surface thrombi [15]. Also, spotted white thrombi were noted in the case of sepsis (see Fig 10B). However, pump-

Fig 10. Representative postoperative findings in the NCVC-type ventricular assist system blood pump: (A) No thrombus formation in most cases; (B) spotted white thrombus formation in cases of sepsis; (C) membranous thrombus on the diaphragm; (D) ring-shaped thrombus formation around the valves.

originated serious complications, such as thromboembolism, were not seen.

Comment

The Japanese government has approved two types of VAS, the NCVC type and the Tokyo University type, for commercial release. In the clinical trials, the NCVC-type VAS showed a maximal output of 6.8 L/min in the adult-sized pump and 1.9 L/min in the pediatric one; the mean bypass flow was 4.14 ± 1.04 L/min and 1.43 ± 0.53 L/min, respectively [11]. These pumps had the capacity of substituting for 100% of cardiac function. The Tokyo University-type VAS showed a mean bypass flow of 2.73 ± 0.52 L/min, and the reported limiting factor was the volume to return to the pump [13]. Both pulsatile-type VASs have been proved to be clinically effective, reliable, and durable devices for salvaging a failing heart.

From clinical experience with VASs in Japan, delay of application and heart failure were big concerns for improving the results. The biochemical profiles and microscopic studies of patients with multiorgan failure in whom the NCVC-type VAS was applied indicated that major organs were exposed to prolonged ischemia before VAS application [11, 12]. In patients with heart failure, unre-

coverable heart failure or combined severe right ventricular failure in LVAS was recognized. Because most patients, especially after cardiectomy, had associated right ventricular failure, if an LVAS alone could not maintain the normal circulation with a right atrial pressure greater than 15 mm Hg and catecholamine, an RVAS should have been applied without losing the timing [20]. For unrecoverable heart failure, heart transplantation should have been carried out, but at present it is not in practice in Japan [21]. It should be kept in mind that the decision to use a VAS should not be delayed. It should be applied before major organs, including the heart itself, are irreversibly damaged.

The causes of death in weaned patients included recurrent heart failure and arrhythmia. The timing of removal of VAS was an important factor for improvement of the survival rate. The optimal period of assist varies considerably according to the patient's condition. These two types of VAS allow for long assistance, especially in the NCVC-type VAS (3 months), so a VAS should be removed after sufficient recovery of the failing heart has been realized [22].

In patients with acute myocardial infarction and cardiogenic shock, the weaning rate of patients with LVAS application alone was 40% and the survival rate was 20%,

which corresponds to the result in patients with LVAS application and coronary artery bypass grafting. These results suggest that LVAS application without coronary artery bypass grafting should be considered in the treatment [23, 24]. Among patients with acute myocardial infarction and ventricular septal perforation, half of the weaned patients died. The main cause of death of these patients was multiple organ failure, which was probably caused by the prolonged low cardiac output condition before the procedure. Early surgical procedure with LVAS application should be considered for improvement of the survival rate.

Pulsatile VASs, the NCVC type and the Tokyo University type, have proved to be effective devices for acute profound heart failure including after cardiectomy, and salvage numbers are increasing with improvement in patient selection and early application.

We greatly appreciate the contributions of the members of the investigational hospitals and those in the industry who provided the data in this report.

External Pulsatile Circulatory Support

Moderator: Charles-Julien Hahn, MD

Panelists: William L. Holman, MD, Jack G. Copeland III, MD, and Gerard Champsaur, MD

MODERATOR HAHN: As the start of this session is already delayed, I will try to save some time by asking Dr Holman to give his presentation without preliminary comments.

DR HOLMAN: My talk will concern our experience with an external pulsatile assist device manufactured by Thoratec, Inc. We have had other experiences with the Thermo Cardiosystems device, but it is an *internal* pulsatile assist device. Today I will concentrate only on the Thoratec pump. It is well known that this mechanical circulatory support system is made of an external hard polysulfone shell and a segmented polyurethane pumping sac. Two Björk-Shiley disk valves are placed at the inlet and outlet of the sac, and polyurethane cannulas connect the heart and the great vessels to the device.

One of the problems we had to face, as already mentioned by other speakers, is bleeding at the time of implantation. Especially when patients already have a bleeding diathesis, persistent hemorrhage at the time of operation is not uncommon. Most of our pretransplantation patients are given warfarin sodium to minimize pulmonary thromboembolism. Moreover, these patients often have elevated pressure on the right side of the heart with hepatic congestion and a high prothrombin time. Because of all the blood product transfusions used to control bleeding, we noted that 2 of our 10 patients developed an elevated panel reactive antibody (PRA) titer that at times became quite high. One patient's PRA peaked at 62%. Another patient's PRA was as high as 40%. When the PRA is elevated, it becomes difficult to find a cross-match-negative donor heart. We are now giving as many transfusions as possible through leukocyte filters to minimize the patient's exposure to foreign HLA antigens.

Other solutions to the PRA problem may come from using plasmapheresis to decrease the PRA titer. However, the efficacy of plasmapheresis to decrease the PRA titer has not yet been proved. We used plasmapheresis in one young woman with postpartum cardiomyopathy. She had arrhythmias including episodes of ventricular fibrillation during which flow in the device dropped down to 3 to 4 L/min. This situation was not acceptable for long-term support; therefore, we used plasmapheresis to decrease her PRA titer.

Another patient was doing well on the ventricular assist device and his PRA titer slowly decreased over time. As noted by other institutions, the PRA titer will usually decrease over time.

In long-term circulatory support, anticoagulation is important to prevent clot formation. It is also important to avoid any kinking or pressure on the polyurethane cannulas.

The Thoratec device can cause a low level of on-going hemolysis, with a plasma free hemoglobin level in the range of 5 to 15 mg/dL. Occasionally there is also a decrease in the hematocrit. If the hematocrit is less than 0.20, a transfusion of erythrocytes is usually given. This entails a risk of increasing the PRA titer.

After 3 or 4 weeks of circulatory assist, inflammatory tissue surrounds the heart. We have faced the problem of inflammatory tissue and adhesions in a 19-year-old man who had acute myocarditis. His heart recovered during the period of circulatory assist, and we were able to remove the cannulas of the ventricular assist device without too many problems. But in another patient (let me remind you, these patients are anticoagulated) at the time of cardiac transplantation disseminated intravascular coagulopathy developed and the patient bled to death.

In one pump we found a rim of white thrombus on the mechanical valve. This happened to be a right-sided pump in a patient who had recovery of right heart function after implantation of the pump. Because the pump is heterotopic, there is some competition with the natural ventricle. When the ventricle is in severe failure, most of the blood goes to the pump. But when the heart starts to recover, the pump may not fill as well. This is another reason why anticoagulation is important (prevention of embolism). Any type of pump, if used a long time in a substantial number of patients, will generate thromboembolic complications. A computed tomographic scan of a patient who was assisted during 193 days showed what must have been a septic embolus that made such a neurologic deficit that the pump was discontinued at the family's request.

Cerebral thromboembolism will occur despite the best anticoagulation. We routinely use warfarin sodium after a week. Is it enough? The question is not yet solved.

We had no fixed neurologic deficits in patients with a Thoratec device for periods less than 70 or 80 days. We had one splenic infarct and one transient ischemic attack after 70 days but with a normal computed tomographic scan and a normal neurological examination.

For longer periods of assistance—160 to 190 days—we had some fixed neurologic deficits. In 1 patient we found vegetations in the Dacron conduit with cultures of the blood positive for *Candida*. This patient was treated with amphotericin B for 6 weeks and became afebrile. The white blood cell count was normal and the cultures were sterile, but the pathologist still found organisms hiding

inside the vegetations. I am fairly certain that the cerebral embolus came from this vegetation.

Early infections were very rare with this device, even if it is not statistically validated. When yeast infection occurs, however, it may be an unsolvable problem. It appears that the *Candida* homes in on the Dacron graft, its initial source being from the gastrointestinal tract, especially the oropharynx and esophagus. This is the reason why we adopted Bob Kormos' protocol (University of Pittsburgh): nystatin at the drop of a hat for prolonged periods.

We had, as an unusual complication, a rupture of an outflow cannula, a kind of slow tear that happened after 90 days of support with a ventricular assist device. This patient had a transient ischemic attack; 4 hours later computed tomography was performed, but when he was put on the gantry it was noted that some blood was leaking out of the cannula going to the inflow of the pump. It was, of course, 1 o'clock on a Sunday morning! So we had no choice but to take the patient back to the operating room and remove the ventricular assist device from the apex, put a cannula in the left atrium, and change the aortic graft. The patient left the hospital in good condition. We were looking with the company at possible changes that could happen in the polyurethane or in the wire wrap that runs right up to the edge of the teflon. The tear could be related to the use of peroxide or the povidone-iodine. It may be that the povidone-iodine impregnates the tin solder at the end of the wire and forms an iodide that is a little weaker, giving the possibility for the wire to pop under stress or for some other reasons. The unsoldered wire can unwind and slice through the polyurethane.

To avoid the problem of adhesions, we are using a sheet of Gore-Tex covering the cannulas and the heart underneath the sternum. As the Dacron is attracted to the middle part of the sternum, like a magnet, this sheet keeps the Dacron away so that, when the sternum is reopened with an oscillating saw, there is virtually no chance to get in the Dacron. As an example, after 90 days, the sheet of Gore-Tex could be peeled easily off the heart. As the sheet covers the atrium all the way down to the pulmonary veins, the dissection is done in case a bypass must be quickly installed.

MODERATOR HAHN: Thank you very much, Dr Holman, for this interesting experience with the Thoratec device. Now I should like to ask Dr Champsaur from Lyon to bring the experience of the Institute of Cardiology of Lyon.

DR CHAMPSAUR: In the cardiovascular hospital in Lyon we have supported 18 patients using the Abiomed 5000 system from January 1988 to July 1991. The age ranged from 7 years to 58 years, and the weight from 20 to 90 kg.

Presupport diagnoses were as usual: idiopathic cardiomyopathy in 11 patients and ischemic cardiomyopathy in 3 (2 with acute myocardial infarctions). Two patients had acute graft rejection, and in 2 other patients the device

was implanted 48 hours after a previous cardiac operation. Five patients experienced a cardiac arrest: 1 or more immediately before implantation. Biventricular support was necessary in 17 patients, and a single left support was used in only 1 patient. The bypass was routinely implanted in the periphery and cannulation was as usual using the intraatrial groove, right atrial appendage, the ascending aorta, and the main pulmonary artery for the outflow cannula. The protamine was reversed after coming off bypass and continuous heparin infusion was started when the activated clotting time was found to be less than 140 seconds. It was then slowly adjusted to remain between 150 and 200 seconds. The range of duration for support was between 1 and 11 days, with a mean of 5.5 days.

Some complications have been observed during this period of support, namely, bleeding complications leading to a reoperation in 4 patients, transient neurological deficit in 1 patient, persistent renal failure leading to renal dialysis in 1 patient, and persistent hypothermia in the early patients who we observed. There were, however, no instances of documented infection, pump failure, or thrombosis in the pumps. One death occurred during support on the ninth day owing to undiagnosed chest clotting and tamponade. Seventeen of 18 patients underwent transplantation, and we observed six early deaths within 30 days after transplantation: 2 due to graft failure, 2 due to persistent multiorgan failure, 1 due to delayed tamponade, and 1 due to septic shock. One death occurred on the second month after operation and was caused by cytomegalovirus pneumonia in a patient after acute rejection.

To summarize our experience in this small series, there were 18 patients supported; 17 underwent transplantation. There were six early deaths and one late death after transplantation. And finally, 10 patients were discharged from the hospital and followed up for 8 months to 2.5 years. This device in this experience has been shown to be a safe cardiac support system with no mechanical failure so far and no serious hemolysis; the mean plasma free hemoglobin level remained less than 2 mg/dL, and thanks to the design of the precoated outflow cannula the blood loss now can be reduced. It is an efficient system and it has the ability to restore and sustain circulation in mortally ill patients as shown by the usual parameters. Noteworthy is the fact that normal hemodynamics were maintained in 2 patients experiencing ventricular tachycardia for more than 12 hours, 1 of them being a patient on a single left ventricular support. As we have seen, the system has some limits. As for other external ventricles, those external ventricles would limit the use for an extended duration, although there have been some, as we have recently heard, in long-term support with external ventricles. In this particular case the pump is over-sized for pediatric support.

MODERATOR HAHN: Thank you, Dr Champsaur. Let me first ask the audience if there are some questions.

DR GESLIP (Berlin, Germany): I want to ask Dr Champ-saur, how could you manage after an average pumping time of 5.5 days to get a heart for transplantation? We were never able to do it in such a short time.

DR CHAMPSAUR: This afternoon, we heard another experience from Berlin; they were able to get hearts in a much shorter time than we do. In France, actually, we can have hearts in a few days, as I mentioned, despite the fact that we are starting to observe a donor shortage. This is why we can expect a limitation of this procedure in the future.

MODERATOR HAHN: I would like to make a comment on the cannulation of these different devices. When dealing with extremely sick patients at the real end of their cardiac failure, the fragility of the cardiac cavities is such that we can get dramatic accidents, mainly with the cannulation of the left atrium. I saw that Dr Copeland is putting in the cannulas almost the same way as we did in our series of 35 patients using the Pierce-Donachy device made by Thoratec. Doctor Copeland, where do you put the left atrial cannula?

DR COPELAND: We put the cannula in the interatrial groove just anterior to and perhaps caudal to the superior pulmonary vein, so that we do not compromise the superior pulmonary vein but we know for sure the cannula is in the left atrium.

MODERATOR HAHN: And do you keep your cannula in the atrium or do you put it in the left ventricle?

DR COPELAND: We have tended to keep it in the atrium. We have noted that the exact angulation of the cannula makes a tremendous amount of difference, and on one occasion we have reopened the chest in the operating room to reposition the cannula slightly and change the output by probably 50%. So we think that is a very important part of the operation. A fair amount of attention and fiddling around, I think, needs to take place if you are going to use atrial cannulation.

MODERATOR HAHN: This is exactly what we were doing because it could be such a source of mistakes. The cannulation of the left atrium in these kind of patients is really a major technical problem, and the way Dr Copeland explained how he is putting in this cannula is the safest one, because the tissue in the groove is very good. It does not have the fragility of the rest of the left atrium. We made quite a number of mistakes in the beginning by trying to put cannulas through the appendage or through the apex of the left ventricle.

Most of the patients you showed us were bridged to transplantation with biventricular assist devices, but what about the univentricular device? Did you try, Dr Holman, to assist patients in a nonirreversible heart failure? And what did you do for this kind of patient?

DR HOLMAN: I think that is an important point to discuss when you are making a decision about which type of cannulation technique to use. Assuming that your device gives you a few options, you have to think about the future of the patient. I have had to remove one pump from the apex of the ventricle, and it is a fairly daunting challenge, not so much to get it out but to reconstruct the ventricle with the jagged, torn-up edge that is left. Atrial cannulation has tremendous benefit if you think there is any chance that the heart might recover function. The one patient who I was discussing earlier with Dr Hahn was a 19-year-old who came in with acute decompensation and what we presume was acute myocarditis. My cardiologist actually convinced me to use atrial cannulation. I thought that we would get better flows, which you typically do, using apical cannulation. He said, "Now look, give him a chance. His cardiac index right now is only $1.4 \text{ L} \cdot \text{min}^{-1} \cdot \text{m}^{-2}$ on all these medications and so forth. However, if it is myocarditis and he does improve, we want to take the device out." After about 4 weeks on the ventricular assist device the patient began to show signs of cardiac recovery. The only reason that patient did not receive a transplant was that there was no donor heart available during that time. But his heart went on to recover completely, and the actual explantation of the atrial cannulation was fairly straightforward. So this is an important consideration. I think that you really have to think about it carefully before you put in the device.

Another difficult problem is a patient with a prosthetic valve. But if you think patients are going to fibrillate then you are really forced to go to apical cannulation, because they can fibrillate for a period of time, and stasis thrombosis can develop in the ventricle; if they spontaneously defibrillate they can eject a large amount of thrombus into their bloodstream, and then your superior support is over. I would like to ask the other two surgeons, what would you do with a patient who has a prosthetic aortic valve in place? With good ventricular assist device support that valve is going to be totally closed for extended periods and a large thrombus will develop despite anticoagulation. How would you handle that patient, Dr Champsaur and Dr Copeland?

DR COPELAND: I am not sure. I think that if we were forced into the situation, our tendency would be to run at the lowest output that kept the patient alive and make sure that the valve opened. I think we would anticoagulate the patient as we normally do and hopefully get the device out as early as possible. I think that is a tough situation.

DR CHAMPSAUR: We had this situation in an old woman who had double-valve replacement and was 1 of the 2 patients who was a so-called postcardiotomy patient in our experience. She was on the device for 11 days but there was no thrombosis at the time of explantation and transplantation.

SPEAKER: We supported a 20-year-old nurse about 2 weeks ago who had an urgent aortic valve replacement

and could not be weaned. We supported her with an apical Thoratec ventricular assist device and her heart would not beat at all. We anticoagulated her. She had a St. Jude aortic valve, and we took the first heart available. That took about 2 weeks. At the time of transplantation the aortic valve was absolutely frozen. She had been on anticoagulants including heparin the entire time. The aortic valve could not be forcibly opened with a finger, it was thrombosed so heavily. So I think the answer is to perform transplantation as soon as possible. Some protocols, as a matter of fact, including, I think, Novacor's, indicate that a mechanical valve would be a contraindication to use one of these systems. But we just could not turn down a 20-year-old woman and so we did it.

Could I ask Jack Copeland one other question? He showed those slides showing the transillumination and those little white dots, I guess he called them, which I assume are platelet thrombi. That was sort of fascinating to me because I do not know that we have looked for them but maybe they would have been there in our devices. I wonder if you could use aspirin therapy or dipyridamole or anything else to alter that pattern. How would you plan to deal with that in the future?

DR COPELAND: You know, I think the more I hear about aspirin therapy the more intrigued I am by it. The TCI experience with 50 patients and only one embolus related to the cannula—not to the device—makes you wonder if aspirin is useful. We have been sort of reticent to use aspirin in these patients because we are always thinking ahead to the time of the transplant operation, when having aspirin on board may make things quite difficult. But I agree with your point that perhaps aspirin is a good idea. These are platelet thrombi. There is no doubt about it. We have looked at them microscopically and with scanning electron microscopy and so forth. One of the things that I am going to take back from this meeting is to be a little more aggressive with the use of aspirin.

MODERATOR HAHN: Don't you think that it is coming from the type of biomaterial you use?

DR COPELAND: I do not think it is necessarily related to biomaterial. I think it is more related, at least as we

have mapped these things, to flow patterns within the device. We have found, for instance, if we mobilize the patients early and get them in a vertical position we do not get an uneven filling pattern into the device so that the diaphragm moves symmetrically and we tend not to get deposition of these things. So another item, I think, that is pretty high on our list is mobilizing the patients, getting the patients into the most advantageous physical position to minimize the low-flow areas within the device.

MODERATOR HAHN: About the Thoratec device, we saw an enormous difference in the first series of patients operated on, with this kind of small clots in the sac of the device, and the last series, in which we did not see that anymore, because the polyurethane was changed. It was more hemocompatible than the first ones. There must be something about the technical way the sac is made. In your experience with the Thoratec, what is your opinion, Dr Holman?

DR HOLMAN: When we were approved to use the device they had already moved on to the newer segmented polyurethane, but I have never seen a thrombus formation. That is one problem that we have not had. I should never say never, but at least in our explantation photographs for the Food and Drug Administration we have not, as of this date, noted any platelet deposits in the pumping sac. But let me add from our study of these devices that the segmented polyurethane, when it is wet, is an extremely slick substance. You wonder intuitively how platelet deposit or red thrombus would stay on there very long with an actively moving sac and a bloodstream flow. It points up one of the weaknesses in all studies, which I think are inherent to any clinical study in humans. You will never really know what the incidence of thromboembolism is because a lot of these small aggregates will go out and be clinically undetectable; in fact, unless you do an autopsy that borders on virtually impossible compulsion, you will never see them either. So what we are really counting are clinically evident, and for the most part that is neurologic complications from thromboembolism. The short answer to your question is no, we have not yet seen any aggregates on the biomer.

Internal Pulsatile Circulatory Support

Moderator: Peer M. Portner, PhD

Panelists: William A. Baumgartner, MD, Christian Cabrol, MD, and O. H. Frazier, MD

MODERATOR PORTNER: We are most fortunate to have with us, on the panel, three internationally known experts with a considerable collective clinical experience in implanted pulsatile circulatory support systems. Doctor Christian Cabrol from Hôpital la Pitié in Paris will talk about the Symbion J7 (Jarvik) artificial heart experience. Then Dr O. H. Frazier from the Texas Heart Institute and Dr William Baumgartner from Johns Hopkins will discuss the TCI and Novacor left ventricular assist systems.

The primary purpose of these sessions is to provide a forum to address the practical issues associated with the clinical use of implantable devices. This will only be achieved if there is a dialogue with you, so I encourage your participation. We shall start with a short presentation from each of the panelists. When the program was put together, a videotape was anticipated from Symbion describing the J7 device. The subsequent demise of Symbion left a gap in the video program, and so I have asked Dr Cabrol if he would take that into consideration in his presentation. He will be followed by Drs Frazier and Baumgartner and then comments from the audience.

DR CABROL: Doctor Portner, ladies and gentlemen, I am very happy and very proud to be invited to such an interesting meeting. As Dr Portner said, I will present our experience on the use of the total artificial heart, Jarvik 7. Our experience is based on 58 patients and the implant duration is from 1 to 623 days. Our total experience with this device is more than 1,400 days. As you know, the Jarvik 7 total artificial heart is placed in the pericardial cavity after excision of both ventricles as in conventional heart transplantation. There is a left and right ventricle for each artificial heart. They are connected by drive lines through the skin to an external console. Each ventricle is made of a rigid shell divided into two chambers by a flexible diaphragm. In the blood chamber, blood enters from the atrium through an artificial inflow valve (Medtronic-Hall) and leaves the chamber through an outflow valve to the pulmonary artery or the aorta. The other (air) chamber is connected by a drive line to the external console. The device works on a complete empty mode in each systole.

The implant operation is performed using the usual midline vertical sternotomy. The heart is exposed through the usual incision of the pericardium and conventional cardiopulmonary bypass is set up between the venae cavae and ascending aorta. The heart is excised, leaving as much as possible of aorta and pulmonary artery. On the atrial side, in contrast to transplantation, as much atrium

as possible is left, by transecting the ventricle side of the atrioventricular orifice and excising the tricuspid and mitral valves while leaving enough solid tissue to suture to the device cuff. A running suture is used, usually 4-0 Prolene for the atria and 5-0 Prolene for the pulmonary artery and aorta. Each suture line is inspected to ensure that there is no leak. The left ventricle is connected with the so-called quick-connect made of a Silastic ring; first the atrial connection, then the aortic connection. After that the right ventricle is attached, first at the tricuspid connection and then the pulmonary artery connection. There are two models, one with 100-mL blood chambers, for large patients, and a smaller 70-mL model, which is the model usually used. After placement of the ventricles they are carefully deaired through special deairing buttons. The ventricles are then connected to the console and we calculate the output. For the 70-mL heart the stroke volume is usually 50 mL. So we set up a rate of 100 beats/min, which gives a cardiac output of 5 L/min. Then cardiopulmonary bypass is progressively weaned and the operation completed in the usual way. The drive lines are placed through special skin orifices using a device that permits some motion but avoids the possibility for bacteria to go up the line. There are console control buttons for both right and left ventricles and a spare device in case of problems.

We set the systolic driving pressure of the right ventricle usually to 50 mm Hg, or a little more, the left ventricle usually to 200 mm Hg, the heart rate and the systole/diastole percentage. The different alarms, including output and pumping rate, are also set. A computer controls device operation, showing different curves, like the ventricle filling curves. There is usually a higher output on the left side because of the shunt between the right and the left circulation through the lungs. The filling curve of each artificial ventricle is a velocity curve. Blood enters very rapidly at the beginning of diastole, then more slowly, and the ventricle is never completely filled. This allows for a Starling effect when venous pressure increases. So you can follow the filling of the ventricle, which is very important, but you can also have an idea of the systemic blood volume. The typical curve of a hypervolemic patient is higher than in a hypovolemic patient. So you can correct for this anomaly. It is also possible to look at the filling curve and differentiate normal filling of the right ventricle from very abnormal filling due to compression of the venae cavae by the right ventricle. It is mandatory to reoperate to correct this compression. It is also possible to observe the ejection curve, which is very similar to normal ventricular ejection, with isometric contraction and blood ejection phases. With each beat the

ventricle completes systole with a typical signature of the empty point. In diastole, this curve allows a measure of the systemic vascular resistance. If the curve increases slowly, there is a high systemic vascular resistance indicating the use of vasodilator drugs. Finally, the computer also gives the average cardiac output for each three beats.

The main problem in using this device is infection because of the large amount of foreign material behind the sternum. In our series, this has not been a problem. The second problem is the coagulation. I will discuss this in more detail this afternoon, but I can say that we use a different approach. We have observed that the total artificial heart modifies all coagulation factors. The conventional tests usually do not reflect the perturbation of the coagulation processes. Platelet activity is usually accentuated, there is excess thrombin formation, and there is hyperfibrinolysis. The problem is not to put these patients on an "anticoagulation status" but on a "normal coagulation status," decreasing platelet activity to normal with dipyridamole and then aspirin, giving heparin to compensate the excess thrombin formation, and using aprotinin to stop hyperfibrinolysis. High doses of dipyridamole are used—about 300 mg every 6 hours—and then aspirin at 50 mg a day. To control thrombin formation, small doses of heparin between 10 and 50 mg a day are given intravenously to stop hyperfibrinolysis, and aprotinin is used on the first day at a dose of 1 million units.

Another goal is to have immediate good hemodynamics—a normal cardiac output and normal systemic arterial pressures. Patients are often hypertensive, so we have to use systemic vasodilators. Right atrial pressure is often elevated by device compression of the venae cavae, and must be decreased to avoid impairment of kidney and liver function. It is essential to follow this with the control curves, especially the filling curves. In our experience, after a few hours, there was a minimal manipulation of control parameters and a moderate use of drugs. Finally, we are very pleased with this device, and are still using it in selected indications. We know it very well. It is a simple and safe device and it allows us to wait until transplantation can be done with the patient in an adequate condition. That means when everything is normal, and not in an emergency, so that survival after transplantation, in our experience, has been at least equal to survival after conventional orthotopic transplantation.

MODERATOR PORTNER: Thank you, Dr Cabrol. Doctor Frazier?

DR FRAZIER: Thank you, Dr Portner. I wanted to provide a little more detail about the implantation techniques for the Thermo Cardiosystems internal, pulsatile blood pump, as well as patient management techniques.

We began performing animal research on this pump in the early 1980s. The pump used then was basically the same pump that we are now using clinically, except that the inlet cannula has been considerably shortened in the clinical model. As many of you know, one of the distinguishing characteristics of this pump is the textured blood-contacting surface, which promotes incorporation

of red blood cells, eventually resulting in identifiable endothelial cell growth on the flexing surface of the device.

The first time I used this pump, I placed it extraperitoneally, but this dissection resulted in the development of a large hematoma. Since then, I have placed the pump intraperitoneally; it fits well in the left upper quadrant, anterior to the spleen and to the stomach. The pump is implanted while the patient is on total cardiopulmonary bypass, and the heart is arrested. I like to cannulate the aorta for arterial inflow, but this can also be accomplished through the groin. The midline incision should be extended to the umbilicus to provide an opening large enough to insert the pump. The device is powered by a simple air-driven console. The drive line, which is connected to the console, exits the body anterior to the left superior iliac spine.

When the system is activated, air may be sucked into the inlet tube, so time and patience are necessary in filling the pump to ensure that all the air is removed. Recently, we have also preclotted the inlet side of the graft, and this seems to decrease the problem. Although the pump is big, it fit in a 54-kg man, who was able to eat and to walk without problems. We also like to ensure that the inlet graft is straight, avoiding any angulation, so that it is directed toward the mitral valve. At first, we worried about bleeding from the cannulation site and spent time reinforcing it with extra pledged sutures. We have not seen bleeding from this area, probably because the left ventricle is decompressed, which minimizes stress on the suture line. Finally, we use transesophageal echocardiography intraoperatively to ensure that the inlet cannula is properly positioned.

After completing insertion of the inlet cannula, the distal end of the outlet graft is sewn to the aorta, and the proximal end is connected to the pump. Care is taken to ensure that an adequate length has been obtained. The length can be adjusted by excising an appropriate length and performing a graft-to-graft anastomosis. Patience is necessary to ensure that all of the air is removed from the pump.

After pump function stabilizes, the drive line is exteriorized. The drive line has been well tolerated, and we have seen no clinically significant complications related to externalization of the drive line.

Postoperative roentgenograms of the patients illustrate the markedly decreased dimensions of the heart, compared with preoperative roentgenograms. It is very important to keep the inlet cannula straight as, because of the diastolic flow, any angulation could promote pannus formation. We have seen this complication in 1 patient.

One of the benefits of intraabdominal placement is that a smooth capsule of fibrous tissue forms around the pump, much like the capsule formed around pacemakers. Within 3 weeks of implantation, the pump becomes well encapsulated, and this may diminish the risk of infections. We have seen no infections of the pump.

If at the time of transplantation excessive bleeding is encountered, the pump can be left in place. The donor heart can be sewn in and the skin closed. When the

coagulation parameters have been corrected and bleeding controlled, the pump can be removed. In general, however, we remove the pump at the time of transplantation.

MODERATOR PORTNER: Thank you, Dr Frazier. Doctor Baumgartner?

DR BAUMGARTNER: Thank you, Dr Portner. I have prepared something similar to what Dr Frazier has presented. Actually there are many technical aspects that Dr Frazier has gone over that apply to both Novacor and TCI implantation.

I thought I would pick some steps important in the implantation process. The first is anastomosis of the outflow graft to the ascending aorta. This is done at the lowest position possible on the aorta. After this, the clamp is moved to the graft. The suture line is then tested for hemostasis, usually after creation of the pump pocket. In most of the Novacor implantations the pump pocket is made anterior to the posterior rectus sheath, somewhat different than the intraabdominal approach described by Dr Frazier for the TCI device. This is usually done before bypass. I will talk about preclotting the graft in a minute. Having completed the aortic anastomosis, connections are then made to the pump/drive unit itself. The drive line exits in the right lower quadrant, superior to the anterior iliac spine. One of the technical points in the implantation is to position the outflow graft somewhat into the right chest, which may require releasing some of the diaphragmatic attachments to the costal margin. This will facilitate reoperation when the median sternotomy incision is reopened. Cannulation of the apex of the ventricle is similar to what has been mentioned already. Pledged sutures are placed around the apex. An important aspect is to check for ventricular thrombus, once you core-out the apex and before insertion of the inflow cannulas.

We centrally cannulate in the majority of patients. Placement of two cannulas allows you to look for a patent foramen. As you have seen from some of the earlier presentations, there have been problems with a patent foramen, especially because decompression, obtained on the left side of the heart with the Novacor device, creates very low left ventricular end-diastolic pressures, occasionally in the negative numbers. With a patent foramen ovale (PFO), the right ventricle and right atrial pressure can be higher than the left and therefore create a shunt from right to left. Finally, deairing is extremely important. We start by filling the pump with saline solution through the inflow conduit, before placement in the left ventricular apex. Then we aspirate air from the inflow graft, the left ventricle, and the outflow graft.

One of the major problems with implantation of all devices has been bleeding. The outflow graft has been a particular source of problems. The primary method of preclotting consists of either blood or fresh frozen plasma, thrombin, and cryoprecipitate, repeated three times. The current outflow graft cannot be autoclaved because of the valve housing. Novacor is developing a valved conduit that can be autoclaved. Another technical method would be to cut the outflow graft at its attachment to the

housing, autoclave the graft, and then reattach it. Perhaps a more simplistic explanation for bleeding through the outflow graft is related to the pressure generated in the graft by pump ejection during deairing. In some cases this may force preclot through the graft interstices. This may be a possible mechanism because good graft hemostasis is usually obtained before cardiopulmonary bypass and deairing. It should also be noted that we are usually dealing with a patient who has an element of liver failure with the added effects of cardiopulmonary bypass.

Explantation is fairly straightforward. If the outflow graft anastomosis occupies most of a short aorta, the groin can be cannulated for arterial inflow. After pump removal a large Hemovac is placed to drain the empty pocket.

Probably the biggest advantage of the internal pulsatile device is the ability to mobilize the patient. It has clearly resulted in transplantation patients who are better candidates than before the device was placed.

MODERATOR PORTNER: Thank you, Dr Baumgartner. Perhaps I could begin the discussion by asking the panelists for comments on device selection. How do you decide whether a patient has adequate right heart function for univentricular left heart support? Or conversely, when do you need concomitant mechanical support of the right ventricle?

DR FRAZIER: Well, we have had 2 patients in whom the Bio-Medicus pump was used for right ventricular support, and we were able to wean both patients from the Bio-Medicus pump. This problem underscores the importance of patient selection, which is the most important criterion for clinically successful use of this technology. A patient with elevated pulmonary resistance is at risk for right ventricular overload. The most desirable patients to undergo HeartMate implantation are those whose condition deteriorates as they await transplantation. Ideally, heart failure should have been present for at least 3 months to allow for preconditioning of the right ventricle. We have been giving prostaglandins preoperatively to many patients with high resistance, and this therapy has been helpful in weaning them from bypass.

DR BAUMGARTNER: I think it is actually fairly obvious in the operating room when you are going to need right heart assist. You are unable to fill the device and concomitantly observe a poorly contracting right ventricle. The administration of multiple blood products often causes pulmonary hypertension requiring increased inotropic support. Once again, bleeding is the major complication of this procedure. Perhaps, if we can reduce the bleeding several of these other problems may be less prevalent.

MODERATOR PORTNER: Doctor Cabrol, how would you choose between the total artificial heart and ventricular assist?

DR CABROL: Well, first of all I say the best device is the device you are acquainted with. You can choose any

device you want, but know it very well and do not change from one device to another. In our own experience, we are using the total artificial heart for some specific indications. In a patient with a massive myocardial infarction with septal rupture that is not easily repaired it is of course very easy to replace the heart with an artificial heart. Another indication is when we do not expect heart recovery. In such a case, we prefer the total artificial heart except in a small patient. Then we use an assist device (external or internal), usually the Nippon-Zeon device because it is a very simple device and has many interesting features. It can be run like an intraaortic balloon pump and the nurses can easily use it without any problems. We are interested now, of course, in using the internal device because of the potential for chronic implantation which will be a very interesting application. We have, since last year, a Novacor device and hope to have, in the very near future, the possibility to use the almost totally implantable left ventricular assist device.

MODERATOR PORTNER: Are there questions from the audience? While people are thinking about questions, Dr Frazier, have you had experience with ventricular fibrillation in any of your patients? And what happens?

DR FRAZIER: We have had 2 patients who experienced fibrillation after the pump had been implanted. One of the pumps had been in for 24 hours and the other, for 36 hours. At the point that fibrillation occurred, the patients had recovered from the pulmonary hypertension associated with cardiopulmonary bypass. The pump kept working, although the flows were reduced. Thus, the real key to overcoming right ventricular failure is maintaining low pulmonary vascular resistance. I will never forget (and Jack Norman is here, and he remembers well) the case of a patient in 1978 who had a stone heart. There was no ventricular function at all. The only thing we had was the intraabdominal left ventricular assist device, which we implanted. The patient was a young man with low pulmonary vascular resistance and he was sustained for 5 days without any right ventricular function.

DR BAUMGARTNER: We have had 1 patient who had sustained ventricular tachycardia for up to a week with the Novacor device in place, and it performed very well. Our last patient had ventricular fibrillation in the operating room before being placed on cardiopulmonary bypass for device removal and transplantation. Although pump flow was somewhat decreased, there was no appreciable drop in blood pressure. Pulmonary vascular resistance was less than 2 Wood units.

I was just wondering, Dr Cabrol, as the Jarvik heart is not available, how many times can you use the old ones?

DR CABROL: First I will answer an earlier question. One of the advantages of the artificial heart is not having to take care of fibrillation, tachycardia, or any kind of arrhythmia. Furthermore, it is a fantastic device in the way you can totally control the circulation. Of course, you still must have vasomotor tone. To answer your question,

we have always had enough devices for our use. Because we were using it regularly we have a lot of devices on our shelves. In addition we were able to obtain devices other teams did not want to use anymore. Perhaps Jack Cope-land can tell you about new developments with this device. There is some agreement with the University of Arizona, who will have the right to use the Symbion ventricular assist device and total artificial heart experimentally and clinically. If you need one of these devices, you can call us.

DR TIMOTHY B. ICENOGLE (Spokane, WA): One of the complications with implanting these devices is, of course, bleeding. And with transfusion of blood products comes the risk of exposure to other people's tissue antigens. Do any of the panelists have some suggestions on how to minimize that exposure when you are in one of these bleeding situations? They have resulted in some really disastrous situations with patients trapped on these devices with 100% positive PRAs.

MODERATOR PORTNER: It is certainly true that bleeding is the most common complication with all of these devices.

DR ICENOGLE: We have had no problems with high PRAs, although we have given patients tons of blood. Bleeding is a problem and we have lost patients a couple of days postoperatively because of transfusion of a large amount of blood products and right-sided resistance coming up. I think the most impressive recent experience was in a patient who had been on Inocor for a long time. The platelet count had dropped to about 16,000/ μ L and, in addition, they did not function. No matter how many times we took him back and how many attempts we made, the patient just bled to death. We could not control it. I would be very cautious of Inocor once it starts to affect platelet function.

DR JOHN C. NORMAN (Chicago, IL): I was only going to add to Dr Frazier's comment regarding the patient with a stone heart. It seems like it was a couple of weeks ago—actually, it was Valentine's Day 1978. We had an experience, in the experimental laboratory, of nearly 12 years implanting left ventricular assist devices without cardiopulmonary bypass. I remember our first publication regarding ventricular fibrillation with a left ventricular assist device in place—the animals were standing, with ventricular fibrillation. It was during that period in the laboratory that we examined the permutations of decreasing pulmonary vascular resistance. We found that all we had to do to get enough blood to pump was to increase the right-sided filling pressures to be on the right side of the Starling curve with the failing or fibrillating right ventricle. Ventricular fibrillation during left ventricular assist device implantation does not seem to be a big problem. You can manipulate the right heart. William Pierce had the same sort of experience in Hershey. Much of what has been presented regarding hemostasis has been worked out in clinical cardiac surgery.

MODERATOR PORTNER: Thank you, Dr Norman. Your timing as always is notable. Maintaining a normal systemic output without right ventricular function is essentially the basis of the Fontan procedure—low pulmonary vascular resistance. Any other comments? Questions?

SPEAKER: Have you ever seen a patent foramen ovale (PFO) cause problems with a Novacor? Has that been reported? To me it seems awfully hard to suck blood from the left ventricle. The only time I have gotten in trouble with a PFO was when I was draining the left atrium. But I guess it could.

DR FRAZIER: Patent foramen ovale has been reported as a problem when centrifugal and axial flow pumps are used, as you have just noted. That is the only instance where we have had that experience. I do not know, whether this has been reported with the Novacor.

MODERATOR PORTNER: There have actually been 3 patients with a PFO problem, but not recently. The large right to left gradient that is a result of elevated right atrial pressures and lowered left atrial pressure, secondary to left ventricular unloading, sometimes gives rise to a serious right to left shunt. Two of these patients were severely desaturated, requiring reoperation to close the PFO. The right atrium is now routinely explored for a PFO at the time of device implantation, and repaired as needed.

DR FRAZIER: If the mitral valve is functional, the left atrium will not experience excessive negative pressure. I place a single venous cannula, just as in any left-sided operation. We have a lot of trouble with bleeding in all these patients because of patient factors, as well as those associated with the pump. I know that in France, they have access to fibrin glue. Has that been of some benefit in treating these bleeding problems, Dr Cabrol?

PROF CABROL: But of course, the fibrin glue is very interesting—that is, to seal the suture lines. It is not easy to use on the total surface of a Dacron graft. But for the suture line it is very useful. I would also say that there is a big advantage in the internal ventricular assist devices because they take blood from the left ventricle. They also avoid any compression or problems with atrial cannulas, and this is very, very important. In that respect, the

implantable left ventricular assist device is almost like a total artificial heart on the left side because there is no real ventricular cavity. I think it is a very efficient quality of such device.

MODERATOR PORTNER: Thank you, Dr Cabrol. Doctor Loisançe?

DR DANIEL LOISANCE (Paris, France): Apparently, the bleeding is a real issue, and we are very fortunate in Europe because we can use aprotinin. The mechanism of action of aprotinin is extremely interesting. There are at least two mechanisms. One is the antifibrinolytic action. But the second, and much more important one, permits the normalization of platelet function. Platelets are activated by foreign surfaces and giving aprotinin at extremely high doses permits a return of the platelet function absolutely to normal. We have tried aprotinin in these patients and, just to give you an idea, a recent Novacor patient bled a total of only 150 mL. This has really changed the whole problem. The only thing we do not know for sure is the optimal dosage. We have been using the following protocol at the time of implantation: one million KIU during the operation and then one million KIU per hour for at least 12 hours. There is a lot to learn about aprotinin.

MODERATOR PORTNER: There certainly appears to be an advantage. It is not yet available in the United States, although I believe Dr Rose has used aprotinin in New York. Would you comment, Dr Rose?

DR ERIC A. ROSE (New York, NY): We have found that the way to get aprotinin is to start with another protocol, which for us was lung transplantation. Once you have some in your center it is usually possible to use it in other circumstances on a case by case basis and compassionate need. I will say this though, it is not a panacea. We have used it at the time of transplantation in explanting a device that had been in place for 324 days, I believe. It was a bloody operation despite the aprotinin; the patient required a lot of blood products.

I would also like to comment on the PFO issue. You can detect a PFO with transesophageal echocardiography. Just do a little bubble study before you get started. We have been doing that now too. If it is not there, then do not worry.

Nonpulsatile Circulatory Support: Techniques of Insertion

Moderator: George J. Magovern, Jr, MD

Panelists: Richard W. Wampler, MD, Lyle D. Joyce, MD, and Thomas H. Wareing, MD

MODERATOR MAGOVERN: We have this morning a learned panel to discuss the techniques of insertion of several assist pumps for postoperative circulatory support. The panelists include Dr Richard Wampler, Dr Lyle Joyce, Dr Thomas Wareing, and myself. Doctor Wampler will begin with a discussion of the Hemopump.

DR WAMPLER: Good afternoon, and thanks for your interest in this session. I want to spend some time today talking about some of the user-related issues of the Hemopump such as patient selection and insertion techniques. For those of you who are not familiar with the Hemopump, it is a high-speed turbine pump that spins at 25,000 revolutions per minute driven by an exotic speedometer cable. Blood is pulled from the left ventricle and is injected into the aorta. Soon to be introduced will be a pump that is for sternal or surgical insertion that injects blood into the ascending arch. One of the key features of this device is that it actively decompresses the ventricle as well as supporting the circulation. The Hemopump has a disposable element, pump assembly, and a console for electrical power and fluids that are needed to support the bearing mechanism of the pump. The console weighs about 11.25 kg; it provides all the information the motor needs to run and monitors system performance. An external drive motor is reusable and resterilizable.

Several versions of the Hemopump are in development or in some kind of clinical trial. The first device was intended for femoral insertion. It is about 23 cm in length and 8 mm in diameter. In addition, there is a sternotomy pump that is intended for surgical insertion. It was removed from the initial trials because of a problem with drive cable fracture but it is currently going to be reintroduced for clinical trials after some engineering breakthroughs that have allowed us to get much greater durability out of the drive cable and significantly greater flows from the pump. The sternotomy device has a much shorter cannula and is intended for insertion in the ascending arch. This device has flows of 5 L/min compared with the 3 to 3.5 L/min provided by the femoral device. The Hemopump generates peak velocities of 4 m/s, and we had a lot of concerns, originally, about hemolysis. However, this high-speed device is not a Waring blender for red blood cells, and red cell injury is on the order of one red cell for every 100,000 that pass through the pump.

I want to present a very brief summary of the clinical

results of a cardiogenic shock trial that was conducted in the United States and to briefly summarize the high points of this trial. We accepted 123 patients to the trial and were able to insert the device in about 80% of these patients. Regarding the mean hemodynamic values before insertion of the device for patients for whom we have preinsertion data, at $1.72 \text{ L} \cdot \text{min}^{-1} \cdot \text{m}^{-2}$ the patients met the criteria of less than $2 \text{ L} \cdot \text{min}^{-1} \cdot \text{m}^{-2}$. The pulmonary artery wedge pressure was 26 mm Hg, well over the 18 mm Hg required, and the mean systolic pressure was 11 mm Hg less than the 90 mm Hg required.

Forty-two percent of these patients, for all diagnostic categories, survived to weaning and achieved ventricular recovery, and 27% were 30-day survivors. When this is broken down, although the numbers do not support statistical significance, I think there are some clear trends. Patients with acute myocardial infarction had very good left ventricular recovery (51.7%) and the best survival (34%). Patients who arrested after being weaned from bypass and in whom a catastrophic episode developed in the recovery room had the poorest survival, only 2 out of the total of 14 patients. Patients with cardiomyopathy, rejection of heart transplantation, had a fairly good survival at 30%.

Noninsertion was significantly greater in female patients than in male patients and has been a significant barrier to use. Noninsertion was primarily related to iliofemoral disease and an inability to get the pump up into the abdominal aorta. If it was possible to get the pump into the aorta the majority of patients underwent successful insertion, although in some patients it was difficult to get the cannula around the transverse arch because of a tendency of the cannula to go into the great vessels of the arch. Catheter guidance could be used for this but it is somewhat cumbersome and significantly prolonged the time of insertion. A rare patient could not be placed on support because it was impossible to pass the device past the aortic valve.

Loss of assistance did occur on some occasions and was predominantly due to the following causes: either the cannula was improperly placed or it migrated out of the ventricle. Drive cable fractures did occur and it was also possible, particularly in patients with acute myocardial infarction, for aspiration of preexisting mural thrombus and occlusion of the inflow of the pump to occur. Cannula ejection in the femoral device occurred 12 times in 11 patients. A contributing factor, we believe, in cannula ejection was the development of left ventricular recovery. Ejection generally occurred after patients began getting good contractility and pulsatility, and patients who had

cannula ejection had better survival than the overall group. Many of the patients with cannula ejection underwent removal of the pump without replacement because assistance was no longer needed.

Drive cable fracture is a sudden event that often occurs without warning. It is usually due to excessive bending of the drive cable. Drive cable fracture occurred in about 1 of 20 patients during the trial. It has been a big enough problem that we have redesigned the drive cable and believe that it will be a much less frequent problem in the future. A drive cable fracture will occur in an area of stress concentration that is very sensitive to small bend radii. Minimal stress can be achieved by providing a gentle curve of the drive cable and by attaching the motor to the patient so there is less possibility of kinking the drive cable when moving the patient.

Any device is vulnerable to user difficulties or problems in the field. One pump was returned to us from a patient who had serious hemolysis. On inspection, it was found that a Prolene suture was aspirated into the pump from the surgical anastomosis at the time of pump placement. A Hemopump is a very small-diameter pump so it will be sensitive to aspirate material, and this is something that needs to be very meticulously guarded against at the time of insertion. Also, preexisting mural thrombus can be aspirated into the pump, and that is a major issue in patients with acute myocardial infarction because 25% to 40% of such patients will have preexisting mural thrombus. In our experience, a mural thrombus was present 8 of 11 times in explanted pumps.

I want to spend a little time talking about the insertion of the sternotomy pump because it is the one that is going to be available in this country for clinical trials in 1992. The pump would be in the ascending arch, the tip in the midventricle away from the apex. This is a good device for surgeons because it does not require fluoroscopy for placement. We are recommending that a graft be anastomosed to the aorta for pump placement. The graft should be anastomosed to the outer curve of the ascending/transverse arch and exit the top of the sternotomy wound. Another technique is to tag the drive cable so that you can tell if the device has been inadvertently moved.

One of the difficult issues that we have wrestled, unsuccessfully, so far is proving clinical utility or measuring clinical benefit to the patient. This is necessary to get approval from the Food and Drug Administration (FDA), and this means that it has to be shown that there is benefit to the patient. Just improving cardiac index or improving blood pressure is not sufficient to demonstrate utility. It needs to be shown that patients have better survival, fewer complications, or shorter times in the intensive care unit. In addition, we also have to identify which patients are likely to benefit from the device. It is necessary to prove indications for use and predict what are the likely outcomes. We have done some statistical analysis correlating left ventricular power, although it is not a readily available number, with survival. The left ventricular power is calculated using mean blood pressure, pulmonary capillary wedge pressure and cardiac index, so it is difficult to have in the operating arena. The formula is left

ventricular work index = cardiac index $\times$ (mean arterial pressure - pulmonary capillary wedge pressure) $\times$ 13.6. The normal value is about 3,000. The Hemopump patients for the clinical trials had values less than 1,500. Patients who could not be weaned from assistance and patients who were weaned were separate statistically at a cutoff of approximately 1,000. Also, at the time of preinsertion for patients for whom we could calculate the value, there was a statistical difference between the work index at preinsertion between who could be weaned and those who could not. Survival was characterized by a very marked increase in ventricular power at 24 hours. In fact if a patient did not show a significant increase in ventricular power in 24 hours, the likelihood of survival was very low.

Our next strategy for the FDA is to look at patients at operation who have difficulty being weaned from the roller pump, and we will take these balloon pump candidates and randomize them against the Hemopump to evaluate survivability and potential patient benefit.

MODERATOR MAGOVERN: Experience with the Bio-Medicus pump at Allegheny General Hospital has been ongoing for more than a decade. The first insertion was performed in July 1980, in a 50-year-old woman after double coronary artery bypass grafting with normal left ventricular function who could not be weaned from cardiopulmonary bypass. Since that time, approximately 15,500 adult patients have undergone open heart operation at Allegheny General Hospital from July 1980 to July 1991, and 77 have required ventricular Biopump support.

The Biopump is a centrifugal pump composed of valveless rotator cones made from nonthrombogenic acrylics. These cones impart a circular motion to the blood, generating centrifugal force, pressure, and flow. The hydrodynamically designed flow path of the pump eliminates turbulence, cavitation, and resulting damage to the blood elements. A magnetic drive and a solid housing design prohibit air or contaminate induction.

The advantage of the pump in comparison with the external pulsatile pumps is that the Biopump is commercially available. It is not considered to be a true assist device by the FDA. As such, it has not been approved or disapproved as an assist device and is simply considered an extension of cardiopulmonary bypass. Needless to say, it is much less expensive than any of the federally approved devices.

As we will see, the Biopump provides temporary but adequate hemodynamic support with proper insertion techniques. The major disadvantage of the Biopump is that it is temporary, and cannulation techniques have necessitated that the patient remain bedridden. Ambulation is nearly impossible as the cannulas are secured with pursestring sutures and tourniquets. The cannulas are brought out through the sternotomy incision, making sternal closure difficult. As such, ambulation is impractical and hazardous as it might result in cannula displacement with resultant loss of flow.

Finally, the centrifugal pump provides for nonpulsatile flow. The external pulsatile pumps have been developed

with the assumption that pulsatile perfusion is critical for end-organ survival. It appears, however, that pulsatile flow may not be necessary for end-organ survival. The question remains unanswered. However, our clinical impression at Allegheny General Hospital is that end-organ survival is not dependent on pulsatile flow.

For left heart support, cannulation is achieved via the left atrium through either the left atrial appendage or right superior pulmonary vein, with return via a cannula in the aortic arch. The left atrial cannula is typically a 32F or 34F Sarns venous cannula. The Allegheny General Hospital group has exclusively used the right superior pulmonary vein for draining of the left ventricle. Other centers have described using the left atrial appendage or the roof of the left atrium. In our experience, these approaches are cumbersome and result in troublesome bleeding. The arch cannula is typically a 22F Bard right angle cannula that had been inserted for the open heart procedure.

For right heart support, the pulmonary artery is cannulated with a 22F Bard right angle cannula. It is the identical cannula used to cannulate the aorta. The right atrium is drained with the same cannula employed for the open heart procedure, typically a 51F two-stage Sarns cannula.

The equipment and supplies should include (1) the Bio-Medicus pump console, (2) Bio-Medicus disposable pump head, (3) Bio-Medicus flow transducer, (4) Bio-Medicus disposable flow probe, (5) sterile 3/8 inch $\times$ 3/16 inch tubing (approximately 10 feet), (6) tubing clamps (four), (7) priming solution (typically 3 L of Plasmalyte A), (8) a large sterile basin (5-L capacity), and (9) a battery pack. To initiate left ventricular assist and separate the patient from cardiopulmonary bypass, the following protocol is followed. Cardiopulmonary bypass flow is reduced gradually while the left atrial pressure is monitored by either a left atrial line or pulmonary artery wedge pressure. When the left atrial pressure reaches 20 mm Hg, assist flow is initiated. Cardiopulmonary bypass flow is then discontinued and the venous line is clamped. The aortic arch cannula is clamped, and the cardiopulmonary bypass perfusion line is quickly removed. The Biopump outlet line is then connected to the arch cannula. All air must be excluded from the connection and tubing at this time. Assist flow is initiated and increased incrementally. The total systemic blood flow (native ventricular output plus ventricular assist pump flow) is maintained at $2.2 \text{ L} \cdot \text{min}^{-1} \cdot \text{m}^{-2}$. Left atrial pressure or pulmonary wedge pressure is maintained in the 5 to 15 mm Hg range by volume adjustment.

Most patients will have some degree of right heart failure when the left ventricular assist is initiated. If left ventricular assist pumping cannot maintain a $2.2 \text{ L} \cdot \text{min}^{-1} \cdot \text{m}^{-2}$ cardiac index with good cannula placement and adequate volume, then right heart failure is present and right heart assist may also be required.

Preparation and priming of the right-sided Biopump is completed as described for the left-sided Biopump. The right atrial cannula placed for cardiopulmonary bypass is connected to the inflow line of the second Biopump. The pulmonary artery catheter (typically, a 22F Bard right-

angle aortic arch cannula) is inserted into the pulmonary artery distal to the pulmonic valve and secured with pursestring sutures. Cannulas are brought out through the superior or inferior aspect of the incision. The skin is approximated, whereas the sternum is not. The perfusion lines are secured sutured to the skin and covered with several towels and a large adhesive plastic drape.

If the patient has no underlying rhythm or blood pressure with discontinuation of cardiopulmonary bypass, then one member of the surgical team will have to proceed with open cardiac massage while the other makes the necessary connections for biventricular assist. If the patient does have some ejection, however, open cardiac massage is not necessary and generally the patients have tolerated a brief period of hypotension without neurologic sequelae.

When a patient is on biventricular assist, coordination of the left and right flow rates requires manipulation of the pumps sequentially while closely monitoring the pulmonary artery pressure. The right assist pump flow is gradually increased while the left pump flow is incrementally raised to accommodate the right-sided output. The right assist pump must unload the right ventricle efficiently for the left assist pump to maintain a cardiac index of $2.2 \text{ L} \cdot \text{min}^{-1} \cdot \text{m}^{-2}$. Left atrial pressure should be 5 to 15 mm Hg.

As mentioned previously, there have been 77 patients who have required assist pumping with the BioMedicus pump over the past decade. The vast majority of these patients have had the assist pumps inserted in the operating room. In the early days of the program, however, there were several patients placed on the assist device in the intensive care unit without the aid of cardiopulmonary bypass. Most of these patients had returned from the operating room with stable hemodynamics. Soon thereafter, however, the patient suffered an unheralded cardiac arrest requiring open cardiac massage in the intensive care unit. Cannulas for left and right heart assist were then placed in the intensive care unit. In reviewing this approach, the Allegheny General Hospital group would not recommend placing the cannulas in the intensive care unit without the aid of cardiopulmonary bypass. For people who arrest in the intensive care unit, our recommendation is to return the patient to the operating room as quickly as possible and place the patient on full cardiopulmonary bypass. Open cardiac massage can be performed during transport to the operating room. Placing the patient back on cardiopulmonary bypass ensures adequate perfusion to the brain. In reviewing the experience at Allegheny General Hospital with placing the cannulas in the intensive care unit, the incidence of neurologic injury was significantly greater. Thus, one could assume that placing the cannulas in the intensive care unit required prolonged episodes of hypotension resulting in neurologic injury. Once the patient is safely returned to cardiopulmonary bypass, then the purse-string sutures can be placed with meticulous attention, and the transfer to the Bio-Medicus pump can be done systematically and more safely. After cardiopulmonary bypass, heparin should be reversed with protamine.

After returning to the intensive care unit, the patient is not anticoagulated until clotting studies have normalized, after which administration of heparin is started to maintain activated clotting times greater than 150 seconds. The perfusionist on duty is responsible for performing activated clotting time monitoring and determining necessary heparin doses. Control of nonsurgical bleeding is accomplished by the administration of fresh frozen plasma, cryoprecipitate, and platelets to maintain coagulation profiles within normal limits. A disseminated intravascular coagulation profile should be obtained, and evidence of disseminated intravascular coagulation as determined by thrombocytopenia, hypofibrinogenemia, and increase in fibrin split products should be treated with appropriate blood products.

In the past, the centrifugal pump head was replaced every 48 hours. Over the past several years, the centrifugal pump has been allowed to function for 3 to 4 days with no abrupt failures. Thus, at this point, the pump head itself can be employed for at least 2 days and probably for 3 or 4 days.

Weaning of the assist pump is usually not attempted during the first 24 hours of assist support. Generally speaking, cardiac recovery requires at least 2 days. When the clinical picture is stable and cardiac recovery is suspected, weaning assessment can be completed. To assess left ventricular recovery, the Bio-Medicus pump flow rate is decreased to a rate that produces a rise in left atrial or pulmonary capillary wedge pressure to 20 mm Hg. At the same time, the arterial pressure waveform is monitored for signs of left ventricular ejection. For weaning the right ventricular assist pump, the right-sided pump flow is decreased while the right atrial pressure is monitored. Concomitantly, the pulmonary artery pressure wave form is monitored for evidence of right ventricular ejection. If after 1 minute of reduced flow no native ventricular ejection is apparent, the assist pump flow is returned to previous levels. If ventricular ejection is noted during weaning, a transesophageal echocardiogram is performed at the bedside. Staged weaning is guided by the degree of cardiac recovery as documented by cardiac output and transesophageal echocardiographic results. In addition, if ventricular ejection is noted during weaning, cardiac output can be calculated by both the thermodilution and Fick methods. If native ventricular output minus assist pump flow is greater than 2.2 L/min and all other patient parameters are stable, then the cannulas can be removed in the surgical intensive care unit or in the operating room under strict aseptic technique.

Generally the decision to remove the pumps is made in the operating room. Visual inspection of the heart is paramount with the aid of the Swan-Ganz catheter and the transesophageal echocardiogram. For removal of the pumps, 2,500 units of heparin is generally administered if bleeding has not been a major problem.

Before having Dr Lyle Joyce speak, I will ask the audience for questions for either Dr Wampler or myself. Before accepting questions, I would like to mention that Allegheny General Hospital has used on one occasion the Medtronic/Carmeda extracorporeal membrane oxygen-

ator system. It has just been delivered to Allegheny General Hospital within the past month. As you may know, the system essentially consists of a heparin-coated hollow fiber oxygenator, a disposable pump, sterile tubing, and various heparin-coated cannulas for the femoral artery or the aortic arch, and for the femoral vein or right atrium. In one of the more promising recent breakthroughs in the field of biocompatible materials, the Carmeda group has successfully developed a technique to bond heparin covalently to foreign surfaces. Our patient had undergone orthotopic cardiac transplantation and developed right heart failure after discontinuation of cardiopulmonary bypass. As such, the Medtronic/Carmeda extracorporeal membrane oxygenator system was used with a heparin-coated arch cannula and a heparin-coated two-stage right atrial venous cannula. The patient was maintained on full cardiopulmonary bypass without the use of heparin for 36 hours until another heart was secured. The circuit worked extremely well and there appeared to be minimal bleeding. In addition, the patient maintained excellent neurologic function as well as stable hepatic, pulmonary, and renal function. Thus, if faced with the choice between using the Medtronic/Carmeda system with two cannulas versus the biventricular Biopump system with four cannulas, I think at this point I would favor using the Medtronic/Carmeda system. Are there questions from the audience?

DR ROBERT P. McMANUS (Milwaukee, WI): We have also had experience with the Medtronic/Carmeda circuit and are pleased with it. The only caution I would make is that you have to make sure that your level of antithrombin III does not fall to less than 60% of normal. The antithrombin III level can fall to less than 60% of normal during long cardiopulmonary bypass times. Low antithrombin III levels may result in clotting of the Carmeda system. I have two questions. First, has aspiration of left ventricular thrombus by the Hemopump been a clinical problem? Second, has Allegheny General Hospital successfully exited the Biopump cannulas through the chest wall to close the sternum and allow the patient to possibly be weaned from the ventilator and ambulate?

DR WAMPLER: Aspiration of left ventricular thrombus has not resulted in neurologic injury but it has resulted in precipitous loss of pump flow in pump-dependent patients, resulting in two deaths.

MODERATOR MAGOVERN: The Allegheny General group has in a few patients instituted univentricular or biventricular support by exiting the cannulas through the chest wall and closing the sternum. In these cases the patients have generally not undergone open heart procedures but rather have been placed on a device for treatment of cardiogenic shock. In one instance, the patient was placed on the transplant list.

DR JOSEPH MOTAN (Providence, RI): At our hospital in Providence, Rhode Island, a second femoral artery type cannula is placed in the ascending aorta while the patient

is on cardiopulmonary bypass. Placing the second aortic arch cannula makes the transition to the ventricular assist device more efficient and prolonged episodes of internal cardiac massage are not required. For right ventricular assist pumping, the same cannula is placed through a pursestring suture in the right ventricular outflow tract and then passed through the pulmonic valve. Both of these cannulas are then tunneled underneath the sternum as one would do with a chest tube. The sternum is then closed, and our bleeding problems have been minimal.

MODERATOR MAGOVERN: That approach is attractive. There is no doubt that the aortic cannula is a troublesome site of bleeding. No matter how many pledgeted sutures one places circumferentially about the cannula, it generally bleeds.

SPEAKER: In our community hospital setting, we generally do not open the chest in the intensive care unit to initiate internal cardiac massage. Rather, our group has been able to place the patient on percutaneous bypass. Interestingly enough, when our group has placed a cannula through the infundibulum of the right ventricle and through the pulmonic valve, right-sided assistance has resulted in massive right ventricular distention secondary to pulmonic valve regurgitation.

DR ROBERT EVERETT (Minneapolis, MN): Our approach to placing the patients on the Bio-Medicus ventricular assist systems also uses transesophageal echocardiography. Our group attempts to differentiate between systolic dysfunction and diastolic dysfunction. If the patient has diastolic dysfunction, then our drainage cannula of choice is a metal-tipped right angle cannula placed in the left atrium through the right superior pulmonary vein. If the problem appears to be systolic dysfunction then we put the cannula across the mitral valve. In addition, the cannulas are then exited through separate stab wounds. The sternum is then closed in the standard fashion. This approach has been helpful in avoiding infectious complications and bleeding.

MODERATOR MAGOVERN: Is the metal-tip right-angle cannula an aortic arch cannula?

DR EVERETT: No, it is a 26F DLP right-angle cannula designed as a left ventricular vent catheter. The catheter is placed through the right superior pulmonary vein.

SPEAKER: Our group has used the Bio-Medicus centrifugal pump head for 6 or 7 days without changing the head.

MODERATOR MAGOVERN: Allegheny General has also used the pump head for 3 or 4 days. I do not think it is necessary to change the pump head every 2 days.

SPEAKER: Our group has transferred the patients to the intensive care unit on the operating room table. Soon

thereafter, decubitus ulcers have often developed in these patients. Has that also been the experience at Allegheny General Hospital?

MODERATOR MAGOVERN: Our experience has been very similar to yours. Presently the nurses place a specific decubitus pad soon after the patient's arrival in the intensive care unit.

DR VICTOR A. JEBARA (Paris, France): We have been using a technique designed at the Texas Heart Institute by Drs Duncan and Frazier. Briefly, a bifurcated coated Dacron graft is sewn to the ascending aorta. One limb of the graft is then used to pump blood into the aorta and the other limb is used to place a cannula through the aortic valve to the left ventricular cavity. In Paris, 5 patients have been treated with this technique, and transesophageal echocardiography has demonstrated minimal aortic insufficiency, no aortic stenosis, and excellent drainage of the left ventricle. The technique has also decreased bleeding at the cannulation site and has provided excellent left ventricular drainage. Doctor Magovern, do you have experience with this technique?

MODERATOR MAGOVERN: We have not had experience using Dr Frazer's technique. It is a novel idea. It certainly would allow you to close a chest and bring the graft through the chest wall.

DR ORDINON (Sweden): I have a question for Dr Wampler. If the Hemopump cannula migrates from the left ventricle into the ascending aorta, is it possible to steal blood from the coronary arteries or from the arch vessels?

DR WAMPLER: At present, this problem has not arisen. It is conceivable that if the cannula was near the coronary ostia, it might pull blood out from the coronary ostia. But so far no investigator has felt that this problem has occurred.

MODERATOR MAGOVERN: One last question.

DR RAUL GARCIA-RINALDI (San Turce, Puerto Rico): Doctor Magovern, do you find your patients on the Bio-Medicus pump accumulating a lot of free water, and how do you manage this problem? Do you specifically use a hemoconcentrator in your circuit?

MODERATOR MAGOVERN: Free water accumulation and subsequent total body edema is very common. The Bio-Medicus pump system is entirely preload-dependent. Thus, if there is ongoing bleeding or vasodilatation in the postoperative period, one must continue to give large amounts of volume.

DR JOYCE: At this time I will discuss only our experience with the Sarns and Bio-Medicus centrifugal pumps,

although we have used the Hemopump and are certainly excited about its future as well. Our experience began with the Centromed pump before Sarns purchased and sold it as the Sarns Delfin pump. Rather than giving a systematic description of our use of these devices, I will point out a few of the pitfalls that we have run into over the last several years, try to explain some of the changes that we have made in an attempt to overcome those problems, and then make a few comments about areas that we believe could use further improvements. We have found that if any system is going to work in the postcardiotomy cardiogenic shock setting, it has to be a system that can be very quickly and easily instituted. Invariably, one is at the end of a long case with multiple attempts having been made to wean from the heart/lung machine. At that point, no one on the team is in the mood for an ill-planned flailing attempt to try to get another system set up. Consequently, we have sterile packages at all times with the right lengths of tubing, the pump head, and all that is needed to quickly make a conversion once the decision is made that a ventricular assist device is needed. The perfusionist and the nurses set this up on the back tables while the surgeons are placing the pursestring sutures in preparation for inserting the cannulas. In the past, we had only straight cannulas to use for venous uptake. That created many frustrations in trying to figure out how to get the position just right so that the tubes would exit from the chest cavity in the appropriate direction to avoid any obstruction to the inflow to the pump. Fortunately, several companies have now manufactured angled cannulas with various rotations, such that practically any situation can be handled quite easily. I believe it is important to have a variety of cannulas available. When the decision to use a ventricular assist device is made, the perfusionists pull out an assortment of the cannulas available. We study the size of the heart and the configuration of the chest cavity and then select the one that we believe fits that particular patient best. The arterial cannulas are also now of multiple types. There are some acceptable ones, but I think there is room for improvement in this area. Longer cannulas are preferable in our experience because it is possible to exit them from the subcostal region such that the sternum can be closed more easily.

Initially, we brought all cannulas through the anterior chest wall. I have always believed in closing the sternum and, consequently, many times have needed to cut out a notch on each side of the sternum to bring the aortic cannula out directly through the sternum itself. We often either wire or suture the cannula directly to the bone. We now try to avoid this approach because it does limit the ability to move the patient freely in the postoperative period. With the newer cannulas, it is possible to bring all the cannulas out subcostally so that the sternum can be closed in a routine fashion. I also believe that it is important, if at all possible, to get the patient awake, extubated and moving in the early postoperative period. We certainly do not accomplish that in even a majority of the cases, but I believe that is something we should aim

for. I think with better cannulation techniques and anchoring procedures for these cannulas, it will be possible to do that rather routinely.

How do we prepare for cannulation? We do not prepare every surgical case for the potential need for a ventricular assist. However, we do routinely use a double pursestring suture of 3-0 Prolene in the aorta, and this is adequate to anchor the aortic cannula for initial hook-up of the left ventricular assist device. If a left ventricular vent is used, it is placed through the right superior pulmonary vein. A simple pursestring suture is used for the initial cardiopulmonary bypass run. If a ventricular assist device is needed, we then reinforce this line with a second and third row of sutures using pledgets all the way around such that we can buttress the tissue to the cannula. I agree with Jack Norman's comment this morning that any cannulation site needs to be buttressed with pledgets or some sort of a fringe on the tube that allows the tissue to be anchored directly to it. We have found the use of fibrin sealant very helpful. Many of you are involved in clinical trials for the Immuno Company, which is trying to get approval for the use of fibrin sealant in this country. Even if you do not have the luxury of having the Immuno fibrin sealant available, you can mix your own fibrin glue using equal parts of cryoprecipitate and thrombin. Gluing the sites of the cannulation may help in decreasing the amount of bleeding postoperatively.

The experience that we have had since May 1985 at the Minneapolis Heart Institute using these two pumps is a modest series of 57 patients. About half had left ventricular assist devices and went on to biventricular support. We have had patients supported from 1 to 16 days for an average of 4 days. Our average age is 55 years. The cannulation sites were as follows. In the left ventricular assist patients, the right superior pulmonary vein was thought to be the best spot for the left ventricular assist device uptake, although in some patients with large left atria, the dome of the left atrium between the aorta and the superior vena cava worked nicely. We used the ascending aorta in all patients for the inflow cannula. For right ventricular assist devices, all of our experience consisted of right atrium to pulmonary artery bypassing. Our results are similar to those of others. We have had about 35% of the patients die on the device, 65% were weaned, and 45% were ultimately discharged. There were some late deaths resulting in an overall present survival rate of 44%, with a majority of those patients being in New York Heart Association class I and II. We certainly believe that there is reason for optimism and reason to pursue efforts to make these techniques simpler and more efficient so that we can institute them at an earlier stage.

DR WAREING: I am an advocate of the centrifugal vortex system for several reasons. First, it is the only device available in most hospitals doing cardiac operations. The only devices are strictly investigational. Second, centrifugal pumps are the only devices that many surgeons are comfortable using.

However, as Dr Joyce and Dr Magovern mentioned,

better cannulas are needed. It is critical to close the chest after device insertion to decrease perioperative hemorrhage and infectious sequelae.

To help decrease postoperative bleeding, Dr Pennington's group uses fibrin glue. Thirty milliliters of cryoprecipitate is mixed with topical thrombin and calcium chloride and given in the two-syringe method.

The essence of the issue of pulsatile versus nonpulsatile flow remains problematic. To a certain extent, the issue cannot be easily answered because most patients with these devices are also supported by the balloon pump, which in essence provides pulsatile flow.

St. Louis University is also using transesophageal echocardiography. In the assist pump patients, it is indispensable. Our group is also involved with quantitating and semiquantitating a means to assess ventricular function on line with edge detection analysis and analysis acoustic back scatter. This system is several years from the clinical setting. To assess recovery of ventricular function clinically, our group decreases pump flow while giving an epinephrine challenge of 1 mL (diluted 1:10,000).

Interestingly enough, Dr Pennington does not believe advanced age (more than 65 years) should be a strict contraindication to assist device placement. We do not use age as a strict criterion for determining ventricular assist device insertion. Our results with patients older than 65 years are comparable with the results in patients less than 65 years of age.

The St. Louis group also supports using the vortex pump as the first line of support for postcardiotomy patients. If ventricular recovery is not dramatic and the patient is a potential transplant candidate, then a more permanent device can be inserted later. The centrifugal pumps are particularly useful in the first several days postcardiotomy. However, the incidence of neurologic and infectious complications rises rapidly after 1 week.

Finally, would Dr Magovern discuss in more detail the use of the centrifugal pump in managing patients with postinfarction ventricular septal defects?

MODERATOR MAGOVERN: In one instance, a patient with a postinfarction posterior ventricular septal defect in cardiogenic shock was treated with insertion of right- and left-sided Biopumps. The ventricular septal defect was not closed. Because the patient was in severe cardiogenic shock with a central venous pressure greater than 20 mm Hg, standard ventricular septal defect closure using cardiopulmonary bypass was considered hopeless as the mortality rate for this group of patients is in excess of 75%. The biventricular support was instituted to explore the possibility that his right ventricular function would significantly improve over 3 to 5 days. Over the course of 5 days, his right ventricle did dramatically recover. On the fifth day of support, the Biopump flow rates were decreased and the right and left ventricles both showed recovery. As such, the devices were removed. Unfortunately, however, the patient suffered a perioperative massive embolic stroke after removal of the devices. The cause of the embolic material was probably mural thrombus. It was a surprise to our group that the patient's right ventricular function would improve after such a massive myocardial infarction. Thus, in patients with a postinfarction ventricular septal defect, in cardiogenic shock, consideration should be given to placing the patients on ventricular assist devices as their myocardium may not be completely infarcted but may be ischemic or stunned. With 3 to 5 days of support, the ischemic or stunned myocardium may recover to the point that the patient could survive. In retrospect, however, it may have been more prudent to close the ventricular septal defect at the time of the device insertion.

SPEAKER: I enjoyed Dr Joyce's lecture and would like to ask him how he investigates for the presence of a patent foramen ovale at the time of device insertion.

DR JOYCE: Generally, our group has not opened the atrial septum to inspect for a patent foramen ovale at the time of device insertion.

Chronic Left Ventricular Support With a Vented Electric Assist Device

O. H. Frazier, MD

Texas Heart Institute, Houston, Texas

Based on the success of the pneumatically powered HeartMate (Thermo Cardiosystems Inc, Woburn, MA) left ventricular assist device, researchers at the Texas Heart Institute have begun conducting clinical studies of the vented electric model in bridge-to-transplantation procedures. Like the pneumatic device, the electric device is implanted intraperitoneally, but the blood pump is powered through a percutaneous lead that is connected to two rechargeable batteries. The batteries are worn in a shoulder holster; thus, patients are not tethered to a

control console and are fully mobile. Two patients are currently undergoing left ventricular support with the vented electric HeartMate (duration of support, 315 days and 112 days) as they await cardiac transplantation, and they seem to be medically fit for outpatient care and follow-up. This technology may eventually allow selected patients to receive long-term support as a substitute for cardiac transplantation.

(*Ann Thorac Surg* 1993;55:273-5)

The success of the pneumatically powered HeartMate (Thermo Cardiosystems Inc, Woburn, MA) left ventricular assist device (LVAD) has encouraged researchers in the field of mechanical circulatory support [1, 2]. This LVAD has been used in staged cardiac transplant operations, with the longest duration of support at the Texas Heart Institute being 233 days. We have found that patients are restored to better health as a result of improved circulation and, thus, end-organ function. Moreover, treatment with the HeartMate has been associated with a low risk of thromboembolic complications and infection. Currently, our research efforts are focused on the next generation of this technology, the vented electric HeartMate LVAD, which not only incorporates the best features of the pneumatic model, but also improves upon it by offering full patient mobility. This article will describe the vented electric LVAD and will provide a brief overview of our clinical experience.

Material and Methods

Description of Vented Electric Left Ventricular Assist Device

The HeartMate-1000 vented electric LVAD consists of an abdominally implanted blood pump and an external power source [1, 2]. The dual-chambered blood pump is housed within rigid titanium and measures 11.2 cm in diameter and 4.0 cm in thickness. The pumping chamber of the blood pump is capable of providing a maximum stroke volume of 83 mL, and the other chamber contains the electric motor. A polyurethane diaphragm that is bonded to a rigid pusher-plate separates the chambers. The inlet and outflow cannulas each contain a one-way,

porcine xenograft valve (Medtronic Blood Systems, Irvine, CA) to ensure unidirectional flow through the pump.

The vented electric LVAD receives power through a percutaneous lead, which is attached to a controller. The LVAD can be powered either by two lead-acid batteries, which are worn in a shoulder holster, or by a stationary control console. The control console can also recharge extra batteries.

The blood pump operates in either a fixed-rate or automatic mode. In the fixed-rate mode, the device pumps blood at a uniform rate and, thus, delivers a steady volume of flow. In the automatic mode, the pump ejects blood when the blood chamber is filled to 90% of its capacity, and, thus, the volume of flow varies in response to systemic circulatory requirements. The motor completes a single rotation for each pump ejection.

As in the pneumatic HeartMate, the electric LVAD features textured blood-contacting surfaces that promote formation of a stable biologic lining [3]. This lining has helped to reduce the risk of thromboembolic complications.

Implantation Technique

The vented electric LVAD is implanted in the same manner as the pneumatic LVAD, and the techniques have been described in detail [4, 5]. The operation begins with a median sternotomy incision, extending to above the umbilicus, after which cardiopulmonary bypass is instituted through standard techniques.

The left ventricular apex is cored with a special circular knife; then, the ventricular opening is reinforced with a sewing ring. The pump is placed intraperitoneally in the left upper quadrant, just below the diaphragm (Fig 1). An incision in the diaphragm allows the inlet cannula to be tunneled from the blood pump to the left ventricle. Pump outflow is achieved by anastomosing the distal end of a preclotted, woven Dacron graft to the ascending aorta,

Fig 1. The vented electric HeartMate is implanted intraperitoneally. Power is provided through a percutaneous electrical lead. The rechargeable batteries are worn in a shoulder holster.

end-to-side, then connecting the proximal end to the pump. The electrical lead and vent tube are then tunneled percutaneously and exteriorized through the left lateral abdominal wall.

To begin left ventricular assistance, the pump is operated manually until air has been removed from the heart, the outflow graft, and the blood pump. Initially, the pump is set to operate at 50 beats/min; then, the rate is gradually increased, until an adequate volume is being delivered through the pump. Cardiopulmonary bypass flow is gradually reduced. Finally, a mediastinal tube and pleural tubes are inserted, and all incisions are closed.

Patient Management During Support

Experience obtained with the pneumatic HeartMate guides our current management of patients on the electric device. Once patients are hemodynamically stable, they are weaned from all vasoactive drugs and from mechanical ventilatory support. As soon as patients resume oral intake, they are placed on an antiplatelet regimen, consisting of aspirin (80 mg, once daily) and dipyridamole (75 mg, three times daily). Sodium warfarin is used if conventional indications, such as a pulmonary embolism, exist.

The major therapeutic goals include early mobilization of the patient, adequate nutritional support, and elimination of potential sources of infection. A physical therapist works with the patient as soon as possible to begin an

exercise program, often beginning in the intensive care unit. As the patient adjusts to the implantable blood pump, a registered dietician ensures that the patient's nutritional requirements are being met. To prevent infection at the site of the percutaneous lines, the area is cleaned three times daily with half-strength peroxide and saline solution and covered with a thin film of silver sulfadiazene. All intravenous lines and catheters are removed as soon as medically possible.

Evaluation of Pump Effectiveness

Pump parameters are adjusted to obtain physiologic flows of approximately 5 L/min. Hemodynamic data and laboratory values are monitored to verify efficacy of LVAD support. Serum creatinine and blood urea nitrogen levels are used to assess kidney function, and bilirubin levels are used to assess liver function. The pump's effect on blood components is monitored by measurement of hemoglobin level, plasma free hemoglobin level, and platelet count.

Study Criteria

In February 1991, the Food and Drug Administration granted the Texas Heart Institute approval to conduct five clinical implants with the vented electric HeartMate. As in the case of the pneumatic HeartMate device, only patients awaiting cardiac transplantation can be accepted into the study [1]. Patients are qualified to undergo staged transplant procedures with the HeartMate when their hemodynamic status continues to deteriorate, despite treatment with standard measures, including medical support, intraaortic balloon pump support, or both. The hemodynamic criteria for treatment include a pulmonary capillary wedge pressure of 20 mm Hg, with either a cardiac index of $2 \text{ L} \cdot \text{min}^{-1} \cdot \text{m}^{-2}$ or less or a systolic blood pressure less than or equal to 80 mm Hg.

The HeartMate cannot be used when a condition that would preclude cardiac transplantation is present. Exclusion criteria include severe pulmonary hypertension, severe renal dysfunction, and severe hepatic dysfunction. Finally, the size of the implantable pump precludes use in a person with a body surface area greater than 1.5 m^2 .

Results

Between May 1991 and April 1992, 4 patients with idiopathic cardiomyopathy underwent implantation of a vented electric HeartMate LVAD. Their average age at the time of implantation was 47 years, and the average body surface area was 2.16 m^2 (range, 2.09 m^2 to 2.26 m^2).

Treatment is on-going in the second and fourth patients in this series. Patient 2, a 33-year-old man, has been supported for 315 days, and patient 4, a 49-year-old man, for 112 days. Kidney and liver dysfunction in these patients have been reversed, as assessed by comparing laboratory values obtained before and after implantation (Table 1). Each patient's overall medical condition has also improved, as evidenced by an upgrade in New York Heart Association functional class status from class IV before implantation to class I after implantation.

The first patient, a 52-year-old man, was supported for

Table 1. Improvement in Kidney and Liver Function in Patients Receiving Continuing Treatment

Variable	Patient 2		Patient 4	
	Before	3 months	Before	3 months
Kidney function*				
Serum creatinine (mg/dL)	0.9	0.9	4.2	1.5
Blood urea nitrogen (mg/dL)	15	11	43	10
Liver function*				
Total bilirubin (mg/dL)	4.2	0.5	1.8	0.7

* Laboratory values shown were obtained before left ventricular assist device treatment and 3 months after left ventricular assist device treatment was initiated.

14 days, with the average pump index being greater than $2 \text{ L} \cdot \text{min}^{-1} \cdot \text{m}^{-2}$; however, he had irreversible end-organ dysfunction related to massive operative and peri-operative hemorrhage (>100 units), which resulted in death. The third patient, a 54-year-old man, died intraoperatively of hemorrhage.

Comment

Two of our patients continue to receive left ventricular support with the vented electric HeartMate because of the inability to locate suitable donor hearts for cardiac transplantation. Despite the long duration of support in patient 2, he is in good health and has not experienced adverse consequences. Both patients seem medically fit for outpatient care and follow-up.

Based on our more extensive study of the pneumatic LVAD and on our early experience with the electric LVAD [1, 2], the potential for providing long-term left ventricular support has greatly improved. The outcome of patients undergoing treatment with the pneumatic HeartMate before transplantation compares favorably with that of our historical transplant patients [6]. Despite progress in

the field of cardiac transplantation, the donor heart shortage continues, and posttransplantation complications, such as accelerated coronary atherosclerosis, limit the potential for a satisfactory long-term outcome. Thus, we need to explore alternatives to cardiac transplantation.

For some patients with chronic left ventricular failure, the alternative to cardiac transplantation may be a permanently implantable LVAD. Whereas patients receiving HeartMate treatment as a bridge to transplantation have enjoyed better health, the quality of their lives is expected to improve even further with the electric system, which allows them to move about freely, untethered to control consoles. Ultimately, we hope to discharge LVAD patients from the hospital, allowing them to return to their normal activities at home and at work. This technology may, in selected patients, be adequate for long-term support as an eventual substitute for cardiac transplantation.

I would like to thank Nancy L. Abou-Awdi, RN, MS, for technical assistance and Christine Lanzisera for editorial assistance in preparing this article.

Univentricular and Biventricular Thoratec VAD Support as a Bridge to Transplantation

David J. Farrar, PhD, and J. Donald Hill, MD

Department of Cardiovascular Surgery, California Pacific Medical Center, San Francisco, California

As of October 1991, the Thoratec ventricular assist device (VAD) system has been used in 154 transplant candidates who were in imminent risk of dying before donor heart procurement at 39 medical centers in 10 countries. The VAD system consists of a prosthetic ventricle with a 65-mL pumping chamber made from Thoratec's BPS-215M polyurethane, cannulas for atrial or ventricular inflow and arterial outflow connections, and a pneumatic drive console. The devices can be used for partial or complete support of the pulmonary, systemic, or both circulations. In all patients (average age, 42 years; range, 11 to 64 years), the pumps were placed in a paracorporeal position on the anterior abdominal wall and connected to the heart and great vessels by cannulas crossing the chest wall. Biventricular support was used in 120 patients (78%) and isolated left VADs were used in 34. Average

flow rate was 5.0 ± 0.9 L/min for the left VAD and 4.3 ± 0.8 L/min for the right VAD. The most frequent complications were bleeding (42% incidence, 7% mortality) and infection (36% incidence, 8% mortality). Ninety-eight patients (65%) recovered sufficiently to undergo heart transplantation after 8 hours to 226 days of support (average, 17.5 days), and 3 are waiting on VADs for transplantation. Eighty-two patients who received transplants have been discharged. This is an 84% early post-transplantation survival and a 54% overall survival. The actuarial survival 1 year after transplantation is 82%, comparable with that of conventional heart transplantation. We conclude that these heterotopic prosthetic devices provide an effective method of maintaining blood flow to vital organs until a donor heart can be procured.

(*Ann Thorac Surg* 1993;55:276-82)

The use of unilateral or bilateral prosthetic ventricles and artificial hearts in patients who are in imminent risk of dying before a donor heart becomes available has become a standard method of supporting the circulation before heart transplantation [1, 2]. Bridging to transplantation is a two-step process requiring implantation of the support device and subsequent orthotopic cardiac transplantation. The Thoratec ventricular assist device (VAD) system was first used successfully as a bridge to transplantation in September 1984. We previously presented reviews of the results with this device in the first 29 patients [3] and 72 patients [4]. The following is an updated report of the current experience in 154 patients as of October 1991 who had circulatory support with Thoratec VADs for left-sided support only or for left plus right support as a bridge to heart transplantation. Results from patients with mixed types of support systems, such as Thoratec VADs used in combination with centrifugal pumps, are not included.

Material and Methods

The studies in the United States were conducted under investigational device exemption regulations, with protocol and patient consent forms approved by the institu-

tional review boards and by the United States Food and Drug Administration. Informed consent was obtained from either the patient or next of kin.

Ventricular Assist Device

The Thoratec VAD system consists of prosthetic ventricles with a 65-mL stroke volume, appropriate cannulas for atrial or ventricular inflow and arterial outflow connections, and a pneumatic drive console (Figs 1, 2). The blood pumping chamber and cannulas are fabricated from Thoratec's BPS-215M polyurethane elastomer, a blend of two polymers, one of which provides extensive flex life and strength; the other provides thromboresistance [5]. The pneumatic drive console (see Fig 2) provides alternating positive and negative air pressure to empty and fill the blood pump and has three control modes depending on the needs of the patient: asynchronous (fixed rate), volume (full-to-empty variable rate), and synchronous [6]. The full-to-empty mode was used in most bridge cases, because it automatically adjusts beat rate and thus flow output in accordance with venous return and the needs of the body. These heterotopic prosthetic ventricles are placed in a paracorporeal position on the anterior abdominal wall and are connected to the heart and great vessels with cannulas crossing the chest wall (Fig 3). For support of the left side of the heart, inflow cannulation can be achieved from the left atrial appendage, from the left atrium through the interatrial groove, or from the left ventricular apex, depending on the patient's anatomy or the surgeon's preference. Ventricular assist device outflow is through a polyurethane cannula attached to a preclotted 14-mm polyester graft anastomosed to the

ascending aorta. For support of the right side, cannulation is from the right atrium with return blood flow to the pulmonary artery. Detailed surgical techniques for these cannulation approaches have been previously published [7].

Patient Population

One hundred fifty-four patients awaiting heart transplantation who were in imminent risk of dying before donor heart procurement received Thoratec VADs for left or biventricular support at 39 medical centers in 10 countries. Coronary artery disease (either ischemic cardiomyopathy or acute myocardial infarction) had been diagnosed in 65 patients (end-stage ischemic heart disease in 43 patients and acute myocardial infarction in 22), cardiomyopathy in 73 patients (hypertrophic in 2, known viral in 7, postpartum in 9, and idiopathic in 55), and graft failure after prior orthotopic cardiac transplantation in 8 patients (early failure in 3, late failure in 5). An additional 8 "other" patients received devices (3 with valvular disease, 3 with myocarditis, 1 with doxorubicin hydrochloride toxicity, and 1 with transposition of the great vessels). There were 121 male and 33 female patients with an average age of 42 years (range, 11 to 64 years), an average body surface area of 1.84 m^2 (range, 1.06 to 2.41 m^2) and an average weight of 73 kg (range, 30 to 123 kg).

Preoperative Status

Before the implantation procedure, all patients were receiving maximal inotropic support, 64 (42%) had one or more cardiac arrests, 99 (64%) received cardiac assistance

with intraaortic balloon pumps, and 89 (58%) were receiving mechanical ventilation. Despite this therapy, the average cardiac index was $1.4 \pm 0.9 \text{ L} \cdot \text{min}^{-1} \cdot \text{m}^{-2}$ with a pulmonary capillary wedge pressure of $30 \pm 8 \text{ mm Hg}$. The decision to implant VADs was made when the clinical and hemodynamic status indicated that the patient would probably die before a donor heart could be located.

Results

As of this writing, 3 of the 154 patients remain on Thoratec VADs for circulatory support while a suitable donor becomes available. Results are therefore reported on 151 patients.

Hemodynamics

Blood flow from the VADs maintained the circulation for up to 226 days until a donor heart could be located and heart transplantation performed. Blood flow from the left VADs averaged $5.0 \pm 0.9 \text{ L/min}$ (flow index, $2.7 \pm 0.5 \text{ L} \cdot \text{min}^{-1} \cdot \text{m}^{-2}$), whereas flow from the right VADs averaged $4.3 \pm 0.8 \text{ L/min}$ (flow index, $2.3 \pm 0.4 \text{ L} \cdot \text{min}^{-1} \cdot \text{m}^{-2}$) (Fig 4).

Of the 151 patients who received VADs with the intention of bridging to transplantation, 98 (65%) recovered

Fig 2. The Thoratec ventricular assist device drive console has two independent pneumatic drive modules for univentricular or biventricular support.

sufficiently to receive heart transplants, and 82 of those were discharged from the hospital (Table 1). Thus the early posttransplantation survival was 84% and the overall survival from implantation to patient discharge was 54%. Most (78%) received biventricular support. In 34 patients (22%) univentricular left VADs were sufficient to support the circulation. The survival statistics for the 32 patients with univentricular left VADs (87% after transplantation, 63% overall) were not significantly different than for the 119 patients with biventricular support (83% after transplantation, 52% overall).

Age

The survival statistics divided into three groups according to age are shown in Table 2 (data for 137 patients). Although the overall survival from VAD implantation to patient discharge showed a slight decrease with age (63%

Fig 3. An example of biventricular support is shown with two ventricular assist devices in a paracorporeal position, functioning as right and left prosthetic ventricles. Left ventricular apex cannulation is illustrated in this example, although left atrial cannulation can also be used. Isolated left heart support can be achieved with a single ventricular assist device. (Reprinted from Hill JD, Farrar DJ, Hershon JJ, et al. Bridge to cardiac transplantation: successful use of prosthetic biventricular support in a patient awaiting a donor heart. *Trans Am Soc Artif Intern Organs* 1986;32:233-7, by permission.)

Fig 4. The average ventricular assist device blood flow index during bridging to transplantation is significantly greater than preoperative cardiac index (CI). In addition, left ventricular assist device (LVAD) flow is slightly greater than right ventricular assist device (RVAD) flow.

in patients less than 40 years, 53% in patients in their 40s, and 49% for patients 50 and over), posttransplantation survival for patients 50 and over (83%) was actually better than for patients in their 40s (76%) but not as good as for those patients less than 40 (91%).

Duration of Ventricular Assist Device Support

The median duration of all bridge cases was 7 days (mean, 17 days), and the range was from 1 hour to 226 days. Of note, in the past 12 months the median duration of support increased to 12 days (mean, 23 days). Survival by duration of support is seen in Table 2 (data for 137 patients). There were 69 patients who had VADs for less than 7 days, 43 patients for 7 to 30 days, and 25 patients from 30 to 226 days. The percentage of patients who underwent transplantation was not significantly different (65% to 68%) between the three groups. The posttransplantation survival for those supported less than 7 days (89%) appeared to be greater than that for those supported for 7 to 30 days (79%) or more than 30 days (76%), but that did not reach statistical significance. The overall survival was similar for the three groups (58% to 52%).

Diagnosis

Sixty-three patients (42%) had coronary artery disease diagnosed, and 73 patients (48%) had nonischemic cardiomyopathy (Table 3). The results are almost identical for these two groups. Within the cardiomyopathy group, the patients with diagnosed viral cardiomyopathy did especially well, although the numbers of patients in the nonidiopathic subgroups are too small to draw any conclusions. Within the coronary artery disease group, the 22 patients with acute myocardial infarction had a better survival rate (100% posttransplantation survival) than the 41 with chronic end-stage ischemic disease (70% posttransplantation survival).

Table 1. Overall Survival Statistics for Patients Who Received Thoratec Left or Biventricular Assist Devices as a Bridge to Heart Transplantation^a

^a Does not include data on 3 patients waiting for a transplant at the time of this report.

BVAD = biventricular assist devices; LVAD = left ventricular assist device; Tx = transplantation.

Complications

Complete data on complications are available for 137 patients who received Thoratec VADs for bridging to transplantation (Table 4). Bleeding, the most common complication during the bridge period, was reported in 58 patients (42%). Reoperation to control bleeding was required in 32 patients, and bleeding was reported as the cause of death (Table 5) in 10 patients (7%). Infection was another major complication, occurring in 49 patients (36%) and causing death in 11 patients (8%). Renal failure was reported in 50 patients (36%), 24 of whom required dialysis during the bridge period. Fifteen patients succumbed to multiorgan failure, which was the most common cause of death in patients who did not survive to transplantation. Hepatic failure was reported in 24% of patients. Hemolysis (defined as a plasma free hemoglobin measurement greater than 40 mg/dL) was seen in 26 patients (19%) on the device, usually only transiently in the first week or two. However, only 3 patients required transfusion. Respiratory failure occurred in 24 patients. Nonthromboembolic neurologic events were reported in 19 patients, including 4 patients who died before transplantation of brain death believed in retrospect to be present before VAD insertion. Embolic events occurred in 11 patients (8%), 8 of whom also had infection complications at the same time. Two patients died before trans-

plantation after cerebrovascular accidents. One patient with a unilateral left VAD died before transplantation with right ventricular failure, and 1 patient died when adequate inflow through the left VAD cannula could not be achieved.

Seven patients who underwent transplantation died of graft failure before discharge. Additional deaths reported after transplantation but before discharge from the hospital were caused by infection in 4 patients, bleeding in 3 patients, and rejection in 1 patient.

Actuarial Survival

The actuarial survival for those who underwent transplantation is shown in Figure 5, along with the survival for conventional heart transplantation according to the Registry of the International Society for Heart and Lung Transplantation [8]. The 1-year survival rate for the patients bridged to transplantation with the Thoratec VAD was 82%, compared with 81% for conventional transplantation as reported in the registry.

Comment

Since our last multicenter report [4], the number of bridge to transplantation procedures with the Thoratec VAD has more than doubled from 72 to 154. Approximately two-

thirds of patients implanted have survived to receive a heart transplant (down slightly from three-fourths), whereas the posttransplantation survival through hospital discharge stayed relatively constant (from 83% to 84%) and is comparable with routine heart transplantation without VAD support. The results again emphasize the importance of patient selection and early implantation as the principal factors influencing survival. Patients who died of multiorgan failure and pre-VAD neurologic hypoxia are examples of patients in whom restoration of blood flow with VAD support was too late to reverse preexisting conditions. Unfortunately, it is often clear only in retrospect that the window of opportunity was missed, and making the decision to proceed with early intervention continues to be a challenge. There is continued debate over the best indications for use. The ideal candidate is in imminent risk of dying of irreversible myocardial damage but without end-organ involvement or contraindications to heart transplantation. The hemo-

dynamic guidelines used in the clinical investigation (cardiac index less than $1.8 \text{ L} \cdot \text{min}^{-1} \cdot \text{m}^{-2}$ and pulmonary capillary wedge pressure greater than 20 mm Hg) have been useful for study purposes but sometimes are inappropriate indicators in patients who are clinically deteriorating before satisfying these criteria.

Most surgical teams continue to prefer biventricular devices, which comprised 78% of the implants. As Pennington and associates [9] have reported, there does not appear to be any difference in morbidity or mortality in using biventricular or univentricular devices. Many patients, of course, do very well with isolated left VAD support, as illustrated by the patient with the longest left

VAD support period in this series of 226 days, who underwent successful transplantation and was discharged alive. However, early implantation appears to be especially important for successful univentricular support, because of potential worsening right heart function or increasing pulmonary vascular resistance. Unfortunately, there are no clear-cut predictive guidelines from this study or from other devices on how to decide whether one or two VADs should be used. Often the right VAD is implanted from the onset to assure against potential right ventricular failure, as the risks of the right VAD are considered small compared with potential risks of right heart failure or a reoperation to implant a right VAD at a later time. Biventricular devices are especially indicated in patients with severe, potentially lethal arrhythmias, and they have successfully supported patients with prolonged ventricular fibrillation or asystole.

The principal advantage of the Thoratec VAD System is its versatility. It can be used for univentricular or biventricular support, left heart cannulation can be accomplished through the left atrium or the left ventricular apex, and the paracorporeal approach allows it to be used in a wide range of patient body sizes, the smallest of which in this series was a body surface area of 1.06 m² in an 11-year-old patient. The device can also be used for support pending recovery of the natural heart [10, 11], as well as for bridging to transplantation.

The preferred cannulation method for bridging to transplantation is the left ventricular apex. A greater flow rate can be achieved (5.5 to 6.5 L/min) compared with left atrial cannulation (4.0 to 4.5 L/min), and there is decreased risk of stasis-induced mural thrombus occurring because blood flow continues through the left ventricular chamber and out the apex. However, if cardiac recovery is a possibility, then atrial cannulation, through either the base of the left atrial appendage or the interatrial groove, is the preferred method to avoid damage to the left ventricle during apex cannulation. Atrial cannulation was recently used in a 19-year-old patient with profound heart failure from acute myocarditis, where the original intent

of bridging the patient to transplantation was changed when his cardiac function showed improvement [11]. The patient was weaned from the left VAD after 70 days and was discharged alive with normal cardiac function.

The median duration of VAD support in 1990 and 1991 has increased to 12 days from 4.4 days as we reported before 1990 [4]. The number of patients supported for longer than 30 days also has increased from 14 to 25, and the longest duration increased from 81 to 226 days. Durations of VAD support are directly related to the time required to find a donor heart, which varies considerably, with some centers always finding hearts in a week or two, and others routinely requiring several months.

Because of the uncertainty of the support duration and the realization that infection is one of the major late complications, patient management should emphasize infection control from the onset. There does not appear to be any pattern to the sites or organisms involved, and device-related infections generally are not a major problem. These are usually limited to superficial percutaneous cannulation sites without involvement into the chest even in the longest cases. All attempts should be made to stop bleeding in the initial implant procedure. Not only is bleeding (surgical and coagulopathy related) a major complication in itself, as noted by Gray and associates [12], but reoperations to control bleeding also increase the risk of late infection. Monitoring lines should be pulled and the patient should be extubated as soon as possible, and ambulation and exercise is encouraged [13].

It should be emphasized that preparation and team training are absolutely mandatory for any successful circulatory support program with the Thoratec VAD or any other device. The roles of hospital support staff should be clearly identified and the team organized and trained [14]. Nursing protocols should be set up [15] and continuing education provided to meet the needs of circulatory support patients.

In conclusion, the Thoratec VAD system provides a versatile means of univentricular or biventricular circulatory support as a bridge to cardiac transplantation in critically ill patients, with posttransplantation survival rates comparable with that of conventional heart transplantation.

We gratefully acknowledge the contributions of the numerous investigators and circulatory support teams at the 39 hospitals who participated in this ongoing study.

Use of the Symbion Biventricular Assist Device in Bridging to Transplantation

Scott Lick, MD, Jack G. Copeland III, MD, Richard G. Smith, MSEE,

Gulshan K. Sethi, MD, and Thomas F. Molloy, MD

University of Arizona Health Science Center, Tucson, Arizona

From 1988 to 1991 13 patients received Symbion biventricular assist devices in attempts to bridge them to cardiac transplantation. All 7 of those who had cardiac transplants survived to hospital discharge. One death occurred 60 days after transplantation because of rejection. All other patients who received transplants are surviving. Implant times in this group varied from 10 to 164 days (mean, 55 days). There were two embolic neurologic events and two significant infections, and 2 of the survivors were dialyzed for reversible renal failure

before transplantation. Of those who died on device support, 3 presented on centrifugal pump support. The three other deaths were caused by graft rejection, multiple organ failure, and multiple peripheral emboli. Biventricular assist devices optimally provide cardiac outputs of 4 to 5 L/min, can be quickly inserted often without requiring cardiopulmonary bypass, are easily explanted, and seem best suited for patients weighing less than 80 kg.

(*Ann Thorac Surg* 1993;55:283-7)

Since the first bridge to transplantation experiences [1-3], devices of various types have been used for days to months to support the circulation. The orthotopic pneumatic biventricular device experience has essentially been confined to the Symbion total artificial heart [4, 5]. The heterotopic, paracorporeal pneumatic biventricular support experience has been largely with the Thoratec device (Berkeley, CA) [3, 6], and the left ventricular heterotopic electromechanical experience has been primarily with the Novacor device (Oakland, CA) [2, 7]. Each of these devices as well as several others [8, 9] have been successful in bridging to transplantation, and although none has enjoyed outstanding success with heart recovery after cardiac operation, the univentricular and biventricular paracorporeal devices have had the best record [10, 11].

Our experience with the total artificial heart is reported elsewhere [4], but our favorable experience with the Symbion ventricular assist device in a biventricular configuration has not previously been reported.

Material and Methods

The Symbion acute ventricular assist device is a pneumatically driven, paracorporeal, pulsatile ventricular assist device. This device may be used for left, right, or biventricular support. Since April 1988 we have used the Symbion acute ventricular assist device exclusively as a biventricular device.

The device was used in 13 patients who remained in

cardiogenic shock despite adequate filling pressure, optimal inotropic support, and when appropriate, intraaortic balloon pump counterpulsation. Three patients were transferred from outside institutions on centrifugal assist (2 in a biventricular configuration, 1 with a left ventricular assist device) with intraaortic balloon pump counterpulsation. Some patients were electively placed on the Symbion while awaiting transplantation. Others were placed emergently before or during a transplant evaluation. The devices were used as an extension of other physiological support measures, such as inotropes and intraaortic balloon pumping. Drive mode was asynchronous so as to allow optimal filling of the prosthetic ventricles and thus maximize cardiac output.

Implantation was accomplished without the use of cardiopulmonary bypass in 3 of the 13 patients (patients 8, 9, and 13). For left heart support, inflow is accomplished by insertion of a right-angle 51F cannula into the left atrium through the area between the right superior and inferior pulmonary veins. Blood returns to the patient through a graft sutured to the ascending aorta. For right heart support inflow is achieved through a 51F cannula in the right atrium, and the outflow graft is sutured to the pulmonary artery.

Several distinct orientations of the device were used until the final optimal orientation was adopted (Fig 1). The objective for device orientation is to eliminate the crossing of drive lines in the mediastinum to minimize dead space and the potential for mediastinal infection, as well as to decrease trauma to the skin at the drive line exit sites. Kinks in the drive lines are carefully avoided.

Device rate was adjusted to provide a stroke volume of at least 45 mL but no more than 65 mL (maximum stroke volume, 70 mL). Complete washout at device systole

Fig 1. Current positioning of the Symbion acute ventricular assist device. Note that drawing nipples are not shown because they are on the posterior aspect with this positioning.

minimizes thrombus formation. Maximum vacuum applied was 20 mm Hg. A device rate around 80 pulsations per minute usually allows for optimal filling of the artificial ventricle. Hemolysis correlates directly with drive pressure and can be kept at less than 10 mg/dL plasma free hemoglobin with drive pressures less than 180 mm Hg.

Anticoagulation measures were used in all patients. Dextran 40 at 25 mL/h was used until heparin could be started. Dipyridamole (Persantine; Boehringer Ingelheim, Ridgefield, CT) administration was begun shortly after implantation at 50 to 100 mg orally every 6 hours and usually continued until removal of the device. When postoperative chest tube output became clear, administration of heparin was started and titrated to maintain a partial thromboplastin time at twice control value. Patients in whom long-term support was anticipated were converted to warfarin sodium (Coumadin; Du Pont Pharmaceuticals, Wilmington, DE) anticoagulation to maintain a prothrombin time of 1.5 to 2 times control.

Physical therapy was initiated immediately after implantation. Moving the patients prevented the development of areas of stasis in the artificial ventricle. Patients were generally ambulatory by the fourth postoperative day. Patients were not considered candidates for transplantation until nutritional deficiencies and other organ dysfunction, particularly renal dysfunction, were reversed.

All patients received prophylactic antibiotics directed particularly at staphylococcal organisms. After removal of the device, the mediastinum was assumed to be contaminated and administration of antibiotics was continued for a minimum of 7 postoperative days. A closed irrigation

system using dilute povidone-iodine (Betadine; Purdue Frederick Co, Norwalk, CT) for 2 to 3 days followed by normal saline solution for 1 to 2 days was used in all patients after transplantation. The irrigation system and chest tubes were not removed until culture of the chest tube drainage was negative.

Results

Our biventricular experience includes 13 patients with refractory heart failure (Table 1). Six of these patients underwent heart transplantation after 23, 65, 53, 164, 39, and 33 days of support. A seventh patient required biventricular support at the time of heart transplantation because of immediate graft failure. Her allograft recovered, and her biventricular assist device was removed after 10 days of support. Of these 7, 6 are alive and well and 1 died 2 months postoperatively due to severe acute rejection. He was not placed back on the ventricular assistance. The mean survival is 2.1 years, and the longest survival to date is 3.7 years.

The remaining 6 patients died on the device of a variety of causes after 1, 15, 4, 6, 21, and 35 days of support. Three of these patients (patients 4, 5, and 9) arrived from outside institutions critically ill due to postcardiotomy failure, on centrifugal ventricular assistance with an intra-aortic balloon pump to improve coronary flow. All 3 were placed on the Symbion within hours after arrival, and they died at 1, 6, and 15 days. A fourth patient (patient 10) was placed on the Symbion because of severe rejection of an allograft heart that he had received 48 days previously. He died of cytomegalovirus sepsis after 21 days of support. Patient 7 died of multiple organ failure precipitated by influenza B myocarditis. Patient 13 died of multiple peripheral emboli.

Seven patients had blood cultures that grew bacteria while on the device. Two of these patients' infections were clearly due to intravenous catheter sepsis (patients 8 and 13), which resolved with removal of the catheters and appropriate antibiotics. One appeared to be due to an *Escherichia coli* drive line infection (patient 11), which resolved with local wound care and intravenous antibiotic therapy. Another was the result of a mediastinal *Staphylococcus aureus* infection (patient 2). Both of these patients went on to successful transplantation without postoperative infection. The rest of the patients had isolated positive blood cultures with minimal growth (less than one colony per milliliter), some of which may have been due to contamination, none of which proved to be clinically significant (Table 2).

Of the 7 patients surviving to explantation (6 transplanted, 1 weaned), 4 had some bacterial growth from the mediastinal tissue and prosthesis samples taken upon device removal. However, only 1 patient had consistent growth from multiple samples (patient 2). All ventricular assist device conduits were well incorporated and without clinical signs of infection. All conduit material was completely removed at the time of explantation, and no postoperative infections were due to the devices. Perigraft infection did not cause major morbidity.

Table 1. Patient Profile

Patient No.	Sex	Age (y)	Weight (kg)	BSA (m ²)	Implantation Duration (d)	Hemodialysis	Indication for Implantation	Support Before Implantation	Outcome	Years Alive

12	F	56	73	1.82	33	No	Idiopathic cardiomyopathy	CPS	T	0.7
13	M	59	59	1.69	35	No	Idiopathic cardiomyopathy	...	D	...

BSA = body surface area; BVAD = biventricular assist device; CABG = coronary artery bypass grafting; CPB = cardiopulmonary bypass; CPS = Bard portable cardiopulmonary bypass system; D = died; IABP = intraaortic balloon pump; MI = myocardial infarction; MVR = mitral valve replacement; T = transplantation; W = weaned.

Tiny clots and "plaques" (generally ≤ 1 mm diameter) could be seen inside the ventricular assist devices through the clear housing. They appeared most frequently at the diaphragm-housing junction. These appeared and disappeared from day to day. Disappearance did not correlate with clinical emboli. This phenomenon had been previously reported [12].

Thromboembolic complications developed in 7 patients. Two patients (patients 3 and 11) suffered strokes, but nearly completely resolved their deficits. Another (patient 8) had an episode of amaurosis fugax 7 days after implantation. This corresponded to the accidental discontinuation of his heparin infusion. All 3 of these patients with apparently isolated cerebral embolic phenomena underwent successful transplantation. The other 4 patients had multisystem emboli. Two (patients 5 and 9) were transferred from outside institutions on centrifugal assist devices before Symbion placement. Two (patients 9 and 13) had clots in the left heart at postmortem examination.

Five of the 7 survivors did not require hemodialysis while on the devices (Table 3). Three of these became more "prerenal" while on the Symbion (patients 1, 6, and 12). The prerenal azotemia of patient 12 resolved once her tamponade-producing mediastinal hematoma was evacuated on day 14. Six patients (patients 3, 5, 7, 9, 10, and 11) underwent hemodialysis while on the ventricular assist devices. Their dialysis runs were generally uneventful, but fluid removal goals were often not met due to intolerance of poor venous return to the ventricular assist

devices. Two patients (patients 3 and 11) recovered renal function while on dialysis and went on to transplantation.

There was no correlation between preoperative blood urea nitrogen level and survival (Table 4). Weight did correlate with survival (nonsurvivors mean weight = 83.8 kg; survivors mean weight = 70.7 kg) (Table 5).

Comment

We have employed biventricular support almost routinely since April 1988. Early experience with right heart failure after left ventricular assist device implantation has led us to adopt this approach.

Most of our success has come in the bridge-to-transplantation setting. Our preference of the asynchronous drive mode with the drive rate set at about 80 beats/min may be in part a reflection of this experience. Whereas the *synchronous* mode may allow for better decompression of the native ventricle, the device rate is slave to the native heart rate, which is usually too fast and often too irregular for optimal filling. This limits output. Moreover, higher drive pressures are required to overcome the systolic resistance and shortened ejection periods, therefore increasing hemolysis. Thus, we favor the *asynchronous* mode. We do not expect our transplant candidates' native hearts to get significantly better after a period of ventricular assistance. We do, however, wish to reverse damage to other end-organs such as the liver and kidneys, and thus will sacrifice some cardiac end-diastolic pressure for end-organ perfusion, if necessary.

Table 2. Morbidity and Mortality

Patient No.	Emboli	Reexploration	Viral and Blood Cultures	Mediastinal Infection of Explant	Drive Line Infection	Cause of Death

15	1.1	19	1.1	
		23	1.7	
Average = 32	Average = 1.8	Average = 31	Average = 1.3	

BUN = blood urea nitrogen.

Emergent placement of the biventricular assist devices has not, by itself, been a risk factor in properly selected patients. Three patients awaiting transplantation were placed emergently on the Symbion after bedside stabilization with the Bard CPS portable cardiopulmonary bypass system. All 3 underwent successful transplantation (patients 6, 11, and 12). On the other hand, none of the 3 who arrived from outside institutions on centrifugal devices after cardiectomy survived. In retrospect, these patients were not good candidates based on their initial conditions and delay in arriving at our institution.

We have tried not to use the Symbion in patients who weigh more than 80 kg because of the limited output of the device (approximately 5 L/min). In larger patients, we favor a total artificial heart. Body surface area and preoperative blood urea nitrogen level did not correlate with

Table 5. Body Surface Area and Weight

Body Surface Area (m ²)		Weight (kg)	
Survivors	Nonsurvivors	Survivors	Nonsurvivors
1.72	2.27	65	102
1.65	2.22	59	100
1.55	1.93	54	80
1.74	1.99	64	80
2.36	2.02	110	82
1.82	1.69	70	59
1.82		73	
Average = 1.74	Average = 1.85	Average = 70.7	Average = 83.8

survival, but weight did. However, 3 of the 6 nonsurvivors arrived recently after a cardiac operation in an edematous state, and this may not be a true reflection of their dry weight. Moreover, our longest-supported survivor (164 days) weighed the most (110 kg).

The Symbion acute ventricular assist device has been reliable and durable for our use, which has been predominantly in the bridge-to-transplantation setting. Although infection, hemolysis, and thromboembolism have been associated with the device, none have ultimately limited its usefulness. Proper patient selection requires exclusion of those with preexisting multiple end-organ failure (but not isolated renal and cardiac failure) and intracardiac clots, and possibly those with large body size.

Nursing Care of the Patient on Mechanical Circulatory Support

Moderator: Julie A. Shinn, RN

Panelists: Nancy Abou-Awdi, RN, S. Jill Ley, RN, Jane E. Reedy, RN, and W. Donald Rountree, RN

MODERATOR SHINN: In the not too distant past, nursing care of the patient on circulatory assist was part of the "heroic" measures taken to save a patient who could not be weaned from cardiopulmonary bypass. In the last decade, we have witnessed the development of many devices capable of successful postcardiotomy support and long-term support for waiting transplant candidates. The latter group of patients are no longer strictly critical care patients, but actually can recover from severe heart failure or shock with the support of these devices. Those are some of the issues we would like to discuss today.

We have a distinguished panel of nurse experts, all with extensive experience in circulatory assist. To my right is Nancy Abou-Awdi, RN, who is a Clinical Research Coordinator at the Texas Heart Institute in Houston. Seated to her right is Jill Ley, RN, a Cardiovascular Clinical Nurse Specialist at the California Pacific Medical Center here in San Francisco. Jane Reedy, RN, is well known to anyone active in circulatory assist. Jane is a Clinical Nurse Specialist from St. Louis University Medical Center. And the fourth member of the panel is Donald Rountree, RN, who is a Critical Care Clinical Nurse Specialist from the Humana Hospital-Audubon in Louisville, Kentucky.

Each panelist has prepared a brief address on a separate topic. After the four topics have been presented, we will open up the floor for discussion. Because these topics are all so closely related, we elected to hold our discussion on the care of the long-term patient until the end of the session.

Our first speaker will be Nancy Abou-Awdi, RN, and she will address the transfer of ventricular assist device patients to non-critical care areas.

MS ABOU-AWDI: The therapeutic objective for ventricular assist device (VAD) patients is to support hemodynamics until either recovery of the native heart occurs or a donor heart can be found. Currently, numerous patients are listed for transplantation, and this has considerably lengthened the wait for a donor, sometimes beyond a year. Management objectives of VAD patients have changed to incorporate not only the critical care needs of the acutely ill, but also rehabilitation needs of a patient recovering from cardiogenic shock. Thus, it has become appropriate to consider housing these patients outside of critical care units.

Currently in the United States, there are four systems

being used to support long-term patients who do not require constant critical care. They are the Pierce-Donachy by Thoratec, the Novacor left ventricular assist system, and two HeartMate systems, an implantable pneumatic and a vented electric system. Why do we need to transfer these patients? The main reason is that patients eventually do not require critical care. They reach a point where they are no longer in unstable condition, they do not require pharmacological agents, and there is no further need for the skills of critical care nurses. The other important factor, and probably primary at our institution, is that the psychological stress of being in critical care more or less inhibits patient recovery. If we look at the cost-benefit issue, there is a major difference in the cost of care in a critical care unit versus the general floor. Cost-benefit is something that we are all very concerned about these days.

So what are the criteria for transferring a patient? I did a survey of several centers with my colleagues and we came up with four basic criteria.

Patients considered for transfer must be in hemodynamically stable condition and not be requiring pharmacological support of hemodynamics. It is also important that patients are taking a majority of their calories orally and tolerating their diet. Finally, patients should be ambulatory. The rehabilitation process begins with muscle strengthening of both upper and lower extremities. Patients progress to daily exercise on an inclined treadmill for up to 30 minutes per session. Before we began transferring patients out of critical care, we kept an active patient such as this for months in a critical care unit.

A major key to successful transfer is preparation of the nursing personnel on the general care unit. The idea of accepting a patient on circulatory support to a general care area conjures up visions that are quite frightening to staff who have never cared for such a patient. Staff preparation will vary from center to center. The support personnel are somewhat different, and the nurses function in different ways. Basically you need to provide staff with knowledge about the device. How does it work? What do I do if? They need to know what to do and what not to do in emergency situations. For example, these patients still have end-stage heart disease and will likely have dysrhythmias. Staff need to understand how dysrhythmias might impair pump output and how to respond. Each center has an educational program for their staff. Some are more elaborate than others, but the primary goal is to

develop a staff that is well prepared for any situation they might encounter with these patients.

Usually a simulator for the device or a mock circulatory loop is set up so nurses and circulatory support personnel can get "hands-on" practice. We can simulate various situations so that staff become very comfortable with the system and know what to do if any emergency arises. St. Louis University uses a detailed self-study program for the two systems they use. The self-study addresses the physiologic response as well the function and operation of the consoles. Most of these patients are totally rehabilitated by the time of transplantation. They also need to know about their systems. Most of them are very curious about what to do if anything should happen with their console. So we have taught the patient and a family member how to work the console and how to switch consoles if need be. They know how to use the manual back-up systems and who to call for help. Pittsburgh has taken this same approach with patients and families.

In conclusion, the actual process of transferring VAD patients is simple. The necessary steps to address in your institution before implementing this change are establishing guidelines for transfer and setting up an education program for all personnel involved in the transfer and care of the patient. The next step, as I see it, will actually be discharging these patients from the hospital. Two of my current patients at Texas Heart Institute have been in the hospital 75 days and 110 days and they are ready to get out. They both know more about their devices and how they work than most of the personnel in the hospital.

MODERATOR SHINN: Our next speaker is Ms Jill Ley, from California Pacific Medical Center in San Francisco. She will address the topic of nutritional support and activity guidelines.

MS LEY: The benefits of nutritional intake are now very well documented in terms of reversing protein catabolism, improving wound healing, and promoting immunocompetence. Questions remain, however, as to what to give and how much to give. To answer these questions for VAD patients, one can begin with a nutritional assessment. Traditional measures of nutritional adequacy include estimation of ideal body weight based on standardized height/weight tables and anthropometric measures of mid-arm circumference. These measures, however, can be grossly inaccurate in the cachectic patient in need of diuretic therapy. Once you add about 10 pounds of hardware to the patient, their ideal body weight becomes anybody's guess.

Assessment of caloric requirements has traditionally relied on standardized equations. Our dietitians use the Harris-Benedict equation and factor in components of weight, height, and age to arrive at ideal caloric requirements for our patients. It can be adjusted for physiologic stress, which will more optimally predict the true caloric needs of patients who are critically ill. A newer method is indirect calorimetry, which determines O_2 consumption and CO_2 production. This method allows you to get a more accurate estimate of patient's true caloric needs. I

mention it because we used this technique in one of our patients. It can be done at the bedside in either spontaneously breathing patients or patients who are ventilated. The test takes a period of 15 to 20 minutes. We found something very interesting when we did one of these metabolic studies on a patient who was on a ventricular assist device 3 weeks after implantation. The patient was extubated and ambulatory at the time. The patient's basal energy expenditure was approximately 12.8% lower than had been anticipated. The dietician noted that under normal circumstances the metabolic requirements of a normally functioning heart are approximately 9.2% of your basal metabolic requirements. So it was speculated that perhaps in patients who have devices taking over myocardial function, we may be overestimating their caloric needs. We have not had a chance to repeat this in another patient yet, so I cannot tell you whether or not we will find this in multiple patients. But I thought it was of note.

Once you have calculated caloric needs, actually getting your patients to take in those calories becomes the true battle. It makes sense to try to use the gastrointestinal tract. Recent work has indicated that using early enteral feedings protects the gut flora and the lining of the gastrointestinal tract and can reverse or at least stop the deterioration or atrophy of the gut that occurs in patients who have been hypotensive or in shock. That may in turn prevent septic episodes by maintaining the homeostatic barrier within the gastrointestinal tract. One of the questions I would like to raise for later discussion is whether anybody is using selective gut decontamination protocols with oral antibiotics to maintain gut homeostasis.

I would like to highlight a report from Ms Abou-Awdi's group in Houston. Vega and associates evaluated nutritional intake in 9 patients with left VADs. In these 9 patients, they found that virtually no patients were meeting 100% of their intake by parenteral methods. In addition, when they looked at these data using a scale to evaluate nutritional deficits, 4 of 9 patients were deemed moderate to severely undernourished early after VAD placement. When they later repeated these values, they found that almost all of their patients were able to meet close to 100% of their caloric and protein requirements. Four of these patients were doing that with diet alone. Diet is clearly the preferred method we would like to use to meet nutritional needs.

One problem that interferes with nutritional intake in VAD patients with implantable devices is the feeling of early satiety, even with small meals. Several interventions have been recommended for these patients, including smaller meals and spacing them out more during the day so that patients are able to get adequate intake. Getting your patients away from the hospital room to an area where they can have some privacy and eat in a relatively normal fashion can significantly promote dietary intake. I do not have any data to support this, but common sense says that patients in a more normal environment would be more inclined to eat better. Patients can eat anything and everything they want in our institution. We discourage salt use if they are having problems with failure, but

generally that is not even a problem. Oftentimes patients like beer or wine with meals and we encourage that. We also encourage families to bring food in from home or to order out for favorite foods.

For patients having difficulty meeting nutritional needs with diet alone, most centers are inclined to go with enteral feedings first. This method can provide a tremendous amount of caloric intake. One technique we have used for patients with inadequate oral intake is nocturnal feedings. We might give continuous tube feeds from 8 PM until 6 AM. Patients can get as much as 50% of their caloric requirements with this technique. They are also not so full during the day that they cannot eat a normal diet.

Next I would like to address mobilization of VAD patients and start by pointing out that there is a tremendous spectrum of patients that you will see. How mobile you get these patients is clearly dependent on what type of patient you are starting with. On one extreme, you have the patient with an open chest covered with a Silastic patch and an external device. No one will be anxious to be too aggressive with that patient. Protocols for this type of patient will center around tilting or turning every 2 hours and passive range of motion exercises. A device such as the Johnson & Johnson Hemopump will also restrict aggressive mobilization. The device requires femoral arterial cannulation, which necessitates restriction of hip flexion.

In patients who have implanted devices, you can get much more aggressive with activity. The exercise protocol used in St. Louis mobilizes patients very early. In the first 24 to 48 hours after implantation, patients are turned every 2 hours and range of motion is started. During the intermediate period out to about 5 days, patients begin to get up in a chair. They have had a couple of patients who were actually ambulatory this early. Their earliest patient started ambulating 3 days after VAD implantation. Telemetry pouches are used to support the devices. With the help of encouraging nursing personnel, they are able to consistently get their patients up and moving quite early. Longer-term patients are progressed to stationary bike riding and ambulating with their devices. Patients can begin the more vigorous conditioning with bedside cycling exercises. We have used this technique for conditioning before getting patients up for the first time. It is similar to the way patients are exercised during a cardiac catheterization study. Patients with implanted devices can actually go to a physical therapy suite, get on treadmills, and use other types of exercise equipment.

One caution to keep in mind is that of all these patients have healing sternotomies, and it is important to avoid using upper extremity weights. Our standard sternal precaution protocol restricts lifting more than 5 to 10 pounds for 4 to 6 weeks.

In conclusion, I think future research could address some of these issues I have discussed. A few primary questions are what is the effect of nutrition and aggressive mobility protocols on length of stay or on infectious complications? And how far can we safely go in mobilizing patients on centrifugal devices?

MODERATOR SHINN: I would like to acknowledge and thank Jill Ley for playing a major role in planning this nursing session. Our next topic is infection control measures, which will be presented by Jane Reedy from St. Louis University Medical Center.

MS REEDY: The major infection control measure used at St. Louis University Medical Center is good hand washing. Many years ago, we used reverse isolation and found that it really did not affect the infection rate. So now we simply emphasize good hand washing and meticulous sterile dressing changes. Intravenous sites are changed every 4 days, and tubing changes are made every 2 days. Of course, another important strategy is to get the patient extubated as quickly as possible.

The antibiotic protocol used at St. Louis University includes a cephalosporin if patients have no preoperative infection and have been in the hospital less than 5 days. An aminoglycoside is added if they have been in the hospital greater than 5 days. If patients have had a preoperative infection, the preoperative antibiotic regimen is continued. Administration of these antibiotics is discontinued when our infectious disease team believes it is appropriate. Prophylactic antibiotic administration is stopped after 3 days if there is no clinical sign of infection. Cultures for blood, urine, and sputum are obtained for any temperature greater than 38.3°C. Only clinically significant infections are treated. Obviously, if the patient is in septic shock immediate antibiotic coverage is started. For a superficial wound infection or a fever, we try to wait for culture results before beginning antibiotic therapy.

Within 24 hours of device insertion, VAD dressing changes begin every 8 hours and are cut back to every 12 hours once the drainage has stopped. Site care consists of normal saline cleansing, Betadine spray, and dry dressings applied to the cannulas or drive line site. At the Texas Heart Institute, silver sulfadiazene creme is used after cleansing with half-strength hydrogen peroxide. Currently, Thoratec does not recommend using hydrogen peroxide because of concern that it might affect the integrity of the cannula. At California Pacific Medical Center, dressings are changed twice a day for 4 days, then every other day. A one to ten strength Hibiclens and normal saline solution is used to cleanse the VAD sites. A Kerlex sponge dampened with the solution is packed around the sites. Sites are then covered with an ABD dressing and secured with Montgomery straps. They have had good luck preventing drive line infections with this technique.

Our surgeons place retention sutures around the cannulas or drive line. Sutures are routinely removed at day 7. The retention sutures are a nice idea because they immobilize the cannulas, and this helps to promote good tissue ingrowth around the VAD sites.

One of our patients was supported on a Novacor system for 370 days and had good tissue ingrowth. An infection did not develop in this long-term patient until day 365 of VAD support. It was a superficial *Staphylococcus aureus* infection. He underwent transplantation 5 days later with no postoperative complications. Many of our

patients have some tracking along the drive line or cannulas. In this situation, we cleanse around the site and along the track with a Q-Tip moistened with normal saline solution. It is very important to cleanse down the track and remove all debris. Irrigations with a suction catheter and normal saline solution can be used for deep tracking (>2.5 cm). Good wound cleansing with antibiotic irrigation when local infection is present can forestall the need for antibiotic coverage. Adequate immobilization of the cannula site is important for prevention of drive line infections as well as encouraging tissue ingrowth.

Most of our drive line infections occur in patients who are on the device for longer than 30 days. I would like to discuss 10 of our patients who were on a VAD for longer than 30 days. All 10 patients suffered from end-stage heart disease. Age ranged from 27 to 56 years (mean, 46 years). Duration of VAD support was from 31 to 440 days (mean, 130 days). Drive line or cannula infections developed in 7 of the 10 patients. The infections were primarily *Staphylococcus aureus*. Five of the 7 patients with drive line or cannula infections had development of positive blood cultures and 2 patients also had development of a mediastinal infection. The first positive cultures were obtained 10 to 364 days (mean, 71 days) after device insertion. The percentage of time on antibiotics ranged from 7.8% to 97% of the duration of VAD support. One of the 10 patients supported for longer than 30 days died. However, his death was not related to infection. One patient with a mediastinal infection was weaned from the device after ventricular recovery and discharged from the hospital. Five of the 8 patients who received transplants had a previous infection. Seven of the 8 patients who received transplants were discharged from the hospital. The non-survivor was a woman who had been supported with a Jarvik total artificial heart for 440 days and was on antibiotics 97% of the time for a drive line infection. Mediastinitis was discovered at the time of transplantation. She remained on antibiotics for several months after transplantation before dying at 3 months of renal insufficiency and infectious complications.

Another concern with implantable devices is the potential for pocket infections. Jackson-Pratt drains are used immediately after insertion of the Novacor VAD. In one particular patient, the drain was not discontinued until day 6 after operation. The site was reddened and never healed completely. About 3 weeks after the device was implanted, a fever developed. An incision was made at the old Jackson-Pratt site and purulent drainage was found. The patient was taken to the operating room, and his Novacor pump pocket was opened. *Staphylococcus aureus* was cultured from the site, and 2 weeks of antibiotic coverage was required to sterilize his blood. He remained on intravenous antibiotics until transplantation. Vancomycin wound irrigations were used, and there was evidence of some tissue healing before transplantation. His blood culture had been sterile for 3 weeks when a heart became available, so he underwent cardiac transplantation. *Staphylococcus aureus* and *Candida* were cultured from his pump inflow cannula. He was treated with a 6-week course of amphotericin and vancomycin. Four

weeks after transplantation, he was sent home with a Hickman catheter. The patient went back to work as a secret service agent 3 months after transplantation and was Dan Quayle's bodyguard during the presidential elections in 1988.

Some infections associated with VAD support can be quite terrible but can be controlled with antibiotics and aggressive dressing changes. The patient just discussed had VAD dressing changes every 4 hours until transplantation.

In conclusion, infections are common in patients supported greater than 30 days. If an infection can be controlled, successful transplantation is possible. Multiple antibiotics or antibiotic therapy required for greater than 3 months is associated with reduced chance of survival. *Staphylococcus aureus* is the most common drive line infection that we have encountered in our patient population.

MODERATOR SHINN: Our last panelist is Donald Rountree from Humana Hospital in Louisville, Kentucky. He will discuss psychosocial aspects of care.

MR ROUNTREE: We have made major strides in our knowledge base over the past few years. Our nursing management of these patients has certainly had a major physiologic focus. What I will talk about for the next few minutes is the psychosocial aspects of patient care. I am a very strong believer that there is not a more appropriate health care provider to address the patients' psychosocial problems than the critical care nurse or the nurse in general. When one looks at the literature regarding nursing problems associated with patients on VADs, two problems are mentioned repeatedly. One is anxiety- or fear-related issues and the second is ineffective coping on the part of either the patient or the family. All of the nursing literature related to mechanical circulatory support certainly addresses these two issues. Because there is such a diversity of devices and lengths of support, I advocate that we divide the psychosocial aspects of care into two stages.

First, I will discuss the short-term patient or the patient in the acute stage, followed by the longer-term patient or the patient in the chronic stage of support. I think you will find some distinct differences in the psychosocial issues depending on what stage those patients happen to be in.

In the acute phase of support, the primary focus is the family. Many of these patients are intubated or sedated, or they may even be paralyzed. Therefore, it is the family that is either going through anxiety-related issues or not coping very well. Our major focus needs to be with the family in the first stage. In the longer term phase, or what I call stage two of support, our focus needs to switch and be more geared to the patient. These patients are up, ambulating, eating, exercising, and some are even leaving the hospital.

In the acute phase of support, anxiety and fear are certainly major. There are two reasons why anxiety and fear are very common. Number one, the device is placed as the result of a life-threatening or emergent situation. A most common reaction of the family during this time is to

be fearful or to be very anxious. So our interventions focus on the family. The other reason we have anxiety- or fear-related problems in the acute phase is that there is knowledge deficit. The patient being bridged to transplantation is a little different because during their evaluation they are told of mechanical assistance and the possible need for mechanical assistance. So they, very possibly, are better prepared. In the acute myocardial infarction patient or the postcardiotomy shock patient, it is the family that generally gives consent for the device to be placed. Even though the procedure and the insertion may have been talked about by the nursing staff, what the family actually comprehends during this preinsertion stage is usually very limited. So both knowledge deficit and a near life and death situation exist, which certainly produces anxiety and fear. The second problem seen in the acute phase is an ineffective coping pattern. The degree of this depends partly on the functional level of the family. We deal with a variety of patient populations and a variety of families. Certainly the functional level of the family determines how well they are going to cope with this situation. There are also some factors in the acute phase that certainly contribute to ineffective coping and anxiety. One is possible feelings of hopelessness on the part of the patient and the family. Impaired communication is another factor. Many of these patients remain intubated for several days. There may be some alteration in family function precipitated by the patient's illness.

Most of the time, interventions during the acute phase are simple but important. I just want to highlight some that are particularly important. Number one, nurses need to demonstrate good communication skills and be sensitive to the patient and the family. Allow the patient, if possible, to express fears and concerns. Another important intervention during this time is regular daily conferences with the family. It is vitally important that they be kept informed. I really want to stress the importance of adopting an attitude of honesty and cautious encouragement. In other words, you can be hopeful while being realistic. Providing the family with alternative support systems such as clergy and social services can help provide them with some means to identify coping strategies.

In the long-term phase, anxiety and knowledge deficit will continue to be issues. The focus at this time centers on the patient. A very important issue to address in the long-term patient is a potential sense of powerlessness. There is a very limited amount in the nursing literature regarding this concept. By definition, powerlessness is a state in which the individual perceives a lack of control. There are two major reasons why powerlessness is a very appropriate nursing diagnosis during this long-term phase of support. Number one, there is an uncertainty or a lack of control over when the donor heart will be located. We are seeing longer and longer periods of support until transplantation occurs. Second, patients can develop feelings of powerlessness because they are on a machine to sustain life. Although the majority of the devices are very reliable, there is always the potential for malfunction. Also, patients are hospitalized for an extended period of time. Powerlessness is also related to an

individual's locus of control. The degree of powerlessness may be influenced by whether an individual has an internal or external locus of control. As you know, a person who displays internal locus of control motivates himself and feels like he can control his fate, whereas somebody who has an external locus of control really needs to be motivated by others because he feels what is happening to him is the result of someone else or fate. How severe a patient displays powerlessness may depend on his locus of control. Many patients experiencing powerlessness will exhibit anger, sadness, apathy, or even hostility. Some may have periods of frank depression. Distorted perceptions of reality and withdrawal from activities may be other signs.

So what do we do for these patients? First, we try to eliminate or reduce any contributing factors. The second thing to do is to provide opportunities for the individuals to control their own environment. Interventions include allowing them to sleep at night, extending visiting hours, and maybe providing consistent staffing patterns. Let the patients make some decisions about their care. It is important to determine what kind of locus of control each patient has. If a patient has an external locus of control, then motivate him to make some decisions. If the patient has an internal locus of control, provide him with information that will help him make decisions regarding care. Increasing the patient's knowledge base with teaching and referrals to appropriate sources of information can help to counterbalance their sense of powerlessness or hopelessness. Many patients enjoy becoming very knowledgeable about their devices.

So, in conclusion, the focus of nursing interventions will change as the patient progresses from the acute to chronic stage. The four major nursing diagnoses that will likely be encountered throughout are anxiety, fear, ineffective coping, and powerlessness.

MODERATOR SHINN: We would like to open the session up for discussion. Please identify yourself.

PAM BRUEM (Portland, OR): I want to thank the panel for making sure that this meeting had a nursing section in it. I really appreciate that. At our hospital our team is very involved in the acute phase. I would be interested to hear about the various roles that nurses play in the long-term phase: research, clinical nurse specialists, managers. What are some of those roles, and how are different nurses functioning in these roles?

MS ABOU-AWDI: The role that I have is clinical research coordinator at Texas Heart Institute. The role is really a mixed bag. I am Master's prepared and I have been working in the laboratory for 3 years. My original position required data collection, obtaining informed consent, and going with the patient to operation to document various things that went on. But over time, this position has greatly expanded. The patients more or less demand it. They want to identify with someone who is responsible for the clinical trial, as well as ongoing care. I also participated in changing nursing procedures and policies

so that these patients can be transferred, are able to walk outside of the hospital, go to the cafeteria for their meals, and go to physical therapy. I am still responsible for the entire clinical trial.

MS BRUEM: What do other nurses do on your team?

MS ABOU-AWDI: I am the only nurse on my team. I work at the Texas Heart Institute, which is separate from St. Luke's Episcopal Hospital. The patients on the devices are inpatients at St. Luke's Episcopal Hospital. The primary care givers are the nurses on the transplant unit, either in the coronary care unit or the general transplant floor.

I work very closely with the clinical nurse specialists on the transplant service, and together we devise the protocols to increase the patient's activities over time.

MS LEY: I will just address that real quickly. I am a clinical nurse specialist, and my role starts when we find out a patient is going to have a VAD implanted. Usually it is the family that has given consent, so I meet with the family and give them as much information as they can handle at the time. My role really focuses on keeping them informed, updated, and educated. And the people who work very, very well with the patient are the bedside nurses. We use a primary nursing model, and we have had no problem whatsoever having people volunteer to be primary nurses for these patients. They coordinate care conferences and work out activity schedules for the patients. We usually have very consistent nursing care. It is the bedside nurses who really coordinate those aspects of care for patients.

MS REEDY: We have four members on our circulatory support team. There are two nurses, a biomedical engineer, and a senior research assistant. Once referral is received, we evaluate the patients to see if they are suitable VAD candidates and then confer with the physicians. We are in the operating room when the device is inserted to operate the console and make sure the operating room nurses are comfortable with all the equipment needed for device insertion. When the patient arrives in the critical care unit, we are there for 24 hours or until the patient's condition stabilizes to monitor the console and patient's condition. After that we are available on an "on call" basis. The nurses are trained to monitor the console and provide initial trouble shooting for a console failure. We also make sure that physical therapy starts, medications are ordered properly, and the patient's postoperative course is as smooth as possible. Nursing and patient education is also a major role in our jobs.

MR ROUNTREE: I am mainly involved with the acute stage. Because we use the Hemopump device and centrifugal pumps, I am usually involved with family contact. I go to the operating room and spend time with the critical care staff. I am the major liaison between family and the nursing staff.

CHRIS THOMPSON (Minneapolis, MN): At the Minneapolis Heart Institute we have a variety of devices, five or so now. I think if we bring another device to our nursing staff they are going to throw their hands in the air. How do you keep your nurses excited and interested in keeping up with all these devices?

MS REEDY: We provide inservices twice a year for the nursing staff and have developed a self-study packet that the nurses can go over themselves. As far as how to keep the nurses excited, I do not think they get worked up with the different devices. I think it is very routine for them. They do not really get frustrated, and they do think it is exciting. I do not think motivation of the nurses is a problem at our institution.

MODERATOR SHINN: I would like to ask a question of the group, to whoever, related to the exit site of the cannulas. Do you think that the angle of the exit site has anything to do with the incidence or the frequency of cannulation site infection? I was interested to see the upward angle of the Novacor exit site for the cannula in the St. Louis patient. At Stanford an approximate 45-degree angle downward is used. Would any of you comment on that?

MS REEDY: I cannot say that we have seen a difference in infection. We have seen a difference in patient comfort. There have been a few times when the VADs came out at a strange angle and we had a hard time keeping the pumps supported when the patient got out of bed. The patients may have more pain with certain cannula and drive line positions. It usually occurs when the cannula is coming out at almost a right angle from the body. Some of our earlier patients had cannulas that laid very parallel to the chest, and we did not have that difficulty.

JULIE COLLINS (Oakland, CA): I wanted to add a comment about infections in general. Even though we do see some infections from percutaneous lead sites, that still only represents maybe 5% or 6% of all the infections that are reported in patients on our device. About half of those infections considered device related are from the percutaneous lead, and they tend to be very superficial infections. We have had 4 or 5 patients who have had pump pocket infections that required opening for cleansing and drainage. None of those infections that were device related precluded a patient from getting a transplant. All have been managed successfully. The other question I had for Ms Abou-Awdi was, what are your protocols for who needs to stay in house to handle emergencies for patients on the floors? Is it the staff nurses or do you have a clinical engineer on call 24 hours who handles that?

MS ABOU-AWDI: Basically, it is the nurses at the bedside who do most of the initial trouble shooting. If there is truly a malfunction of some sort that they cannot handle, we have 24-hour circulatory support. It's what we call the "balloon team." They are there for balloon inser-

tions, removals, and cardiac outputs, so they are the first line of defense beyond the staff nurse. We also have research personnel on call 24 hours a day. A back-up console is available for every patient, and the consoles can easily be switched.

BARBARA TYE (Philadelphia, PA): Do you all use gut decontamination, and have you found there is a decreased incidence of infection, bacteremias, or even cannula infections as a result?

MS LEY: Actually, we do not do that with our hearts, but our liver transplant patients have been on a bowel preparation protocol. It is neomycin and mycostatin. There is some work going on with glutamine, an amino acid, that could be added to total parenteral nutrition solutions and facilitate maintaining the gut barrier. But we have not currently started that.

EDITH CLOTH (Denver, CO): What you do when a patient is placed on a device in an emergency situation and the patient ends up not being a candidate for transplantation and is not able to be weaned off the VAD?

MS ABOU-AWDI: The only VAD we use emergently is the Bio-Medicus pump for right or left or biventricular assist. With the HeartMate, the only candidates are bridge to transplantation patients, so if we do not have transplant approval, the device does not go in.

MS LEY: Unfortunately we have been in this position where a device has been placed in a patient and something happens during the period of support that makes the patient an unsuitable candidate. It is a very difficult decision. If you are dealing with renal failure, that is not a contraindication in our institution. We have performed transplantation in 3 patients who were requiring dialysis. Two of them reversed. So we do go ahead and treat specific organ dysfunction. If you are dealing with a brain dead patient, then you are certainly not doing that patient and family any favors by keeping the patient alive. In that situation, there is a team conference where the physicians meet with the family. I think what is really critical is that they understand the reality of the situation. It is a very difficult decision if the patient is deemed to no longer be a candidate. Usually these have been patients with multisystem failure or patients who were essentially brain dead.

Ventricular Assist Devices and Total Artificial Hearts: A Combined Registry Experience

Walter E. Pae, Jr, MD

Division of Cardiothoracic Surgery, Department of Surgery, The Pennsylvania State University College of Medicine, Hershey, Pennsylvania

Data submitted voluntarily to the combined registry for the past 6 years on the use of ventricular assist devices for postcardiotomy cardiogenic shock in 965 patients and for circulatory support in conjunction with cardiac transplantation in 544 patients were analyzed. Of those patients whose ventricular function was expected to recover, approximately 45% were weaned from circulatory support and 25% were discharged from the hospital. Weaning status and hospital discharge were not different regardless of the type of original operative procedure or the pump design used. In the potential cardiac transplant group, 69% ultimately underwent transplantation and

66% were discharged from the hospital. The demographics (age and sex) of this group parallel those of patients undergoing isolated cardiac transplantation, and the 1- and 2-year survival estimates for patients requiring only univentricular support were equivalent to those of patients having isolated orthotopic cardiac transplantation. Ventricular assist devices are able to provide reasonable and safe circulatory support in both the postcardiotomy cardiogenic shock and the bridge-to-transplantation applications.

(Ann Thorac Surg 1993;55:295-8)

For those individuals who are not familiar with the registry, approximately 6 years ago under the auspices of the American Society for Artificial Internal Organs and the International Society for Heart Transplantation, a registry was formed for the clinical use of ventricular assist devices and the total artificial heart. This particular registry is voluntary and has allowed the development of a very large computerized database, which is hopefully representative of general clinical experience. This report encompasses information gathered over the past 6 years in a rather detailed form on the clinical application of these devices in postcardiotomy cardiogenic shock and in conjunction with cardiac transplantation.

Postcardiotomy Cardiogenic Shock

Postcardiotomy cardiogenic shock requiring aggressive mechanical circulatory support occurs in somewhat less than 1% of all postcardiotomy patients. The database referable to this problem, as of December 31, 1990, consisted of 70 reporting centers, 44 of them in the United States and 26 outside the continental US. Of the 965 total applications of devices reported to the registry, 71% were in male patients having a mean age of 56 years. Twenty-nine percent of the patients were female, with a mean age of 53 years. This certainly reflects the male prevalence of coronary artery disease. Circulatory support was provided in these patients for approximately 4 days regard-

less of whether isolated left, right, or biventricular support was used. However, the wide ranges of support times (0 to 69 days) would indicate the necessity for support systems to have some short- to intermediate-term capabilities. Interestingly and without an apparent explanation, patients who were supported with vortex or centrifugal devices were weaned on an average of about 3 days, versus 6 days for those supported with pulsatile devices. There were no statistically significant differences in the mean duration of circulatory support between those patients who were weaned, not weaned, or weaned and discharged from the hospital. However, in approximately 90% of the patients who survived, circulatory support was able to be discontinued by 1 week postoperatively.

If one takes into account the nature of the original operative procedure, statistically the weaning status and hospital discharge rates were not different. Ultimate survival varied from a low of approximately 14% associated with double-valve replacement with or without myocardial revascularization to a high of nearly 30% seen with isolated coronary artery bypass grafting, which represented 53% of device use. Because statistically weaning and discharge rates did not seem to depend on the original operation, the results were analyzed by the type of support, univentricular right or left versus biventricular (Table 1). Four hundred ninety-four patients received univentricular left ventricular support and about 51% of those patients were weaned. One hundred thirty-seven, or 28%, of those patients in whom the device was implanted were ultimately discharged from the hospital. Nearly 39% of those patients receiving isolated right ventricular support (most of these patients had intraaortic balloon pumps as well) were weaned from the devices and about 26% of those patients in whom the device was

Table 1. Overall Results of Ventricular Assist Pumping in Postcardiotomy Cardiogenic Shock

Type of Support	No. of Patients	Weaned	Discharged
LVAD	494	254 (51.4%) ^a	137 (27.7%)
RVAD	121	47 (38.8%)	31 (25.6%)
BVAD	350	132 (37.7%)	69 (19.7%) ^b
Total	965	433 (44.9%)	237 (24.6%)

^a $p = 0.0$ by χ^2 analysis. ^b $p = 0.027$ by χ^2 analysis.

BVAD = biventricular assist device; LVAD = left ventricular assist device; RVAD = right ventricular assist device.

implanted then survived to hospital discharge. Three hundred fifty patients received biventricular support, with 38% of the patients being weaned and 20%, clearly a lower number as compared with isolated support, ultimately discharged. The overall results would therefore indicate that nearly 45% of the patients were weaned from support and 25% of those patients in whom the device was implanted ultimately were discharged. Statistically a higher proportion of those patients receiving univentricular support were weaned with a significant difference and trend toward overall diminished survival with biventricular support. This is easily understood in terms of the severity of the underlying pathology. When outcome was analyzed by pump design in the postcardiotomy application, twice as many patients were supported with the more readily available and clearly less costly nonpulsatile centrifugal devices. In fact, the weaning and hospital discharge rates were not statistically different between the pulsatile and centrifugal devices.

Although the overall hospital mortality rate was about 75%, in those patients discharged, 2-year actuarial survival averaged 82% and did not statistically differ by the type of support originally used. Most importantly, in those patients who survived to hospital discharge, 86% were New York Heart Association functional class I or II.

Complications during assist pumping were common, with multiple complications recorded in individual patients. Univariant analysis indicated that bleeding, disseminated intravascular coagulation, renal and biventricular failure, cyanosis secondary to an unrecognized patent foramen ovale, inadequate cardiac output, and inlet cannula obstruction leading to low cardiac output were associated with the inability to wean a patient from mechanical support regardless of the type of support. When these same events were analyzed by device type, pneumatic pulsatile versus centrifugal in relation to the weaning status, only bleeding was significantly different, with this event being more likely to occur and negatively affect weaning in the vortex pump group. Infection was significantly associated with weaning overall, but was only associated with weaning in those patients with pneumatic devices. This is likely on the basis of the two times longer average support times with the pneumatic pulsatile devices versus the centrifugal devices. When these complications were analyzed in those patients

weaned from circulatory support in an attempt to associate such with hospital death or discharge, only renal failure, perioperative myocardial infarction, and infection had a significant negative impact in a univariant fashion regardless of the type of support or the device used. Biventricular failure, however, reached near significance. Although there was no statistical difference in the rates of weaning based on age, there was a significant decrease in hospital discharge in patients older than 70 years. A 13% salvage rate was recorded. Device dependency was seen only in 8% of unweanable patients, and three-quarters of those device-dependent individuals had no immediate contraindications to transplantation. Staged orthotopic heart transplantation was then carried out in 20 of the 32 patients, with 63% ultimately surviving after transplantation. These results are nearly equivalent to those seen in the standard bridge-to-transplantation application.

In conclusion, the available devices appear to provide reasonable and safe circulatory support with equivalent results in the postcardiotomy cardiogenic shock application with both nonpulsatile centrifugal and pulsatile pneumatic devices. Myocardial recovery and acceptable short-term results can be expected in about 25% of patients who otherwise would have been expected to die. Complications during support are frequent, but those limiting patient survival are not exclusively device-related. In fact, some are technical errors in cannula positioning, unrecognized patent foramen, or unrecognized or inadequately treated right ventricular failure. Many are patient-related based on underlying disease, the surgeon's ability to correct myocardial pathology, the patient's physiologic reserve, and the duration of shock, as well as cardiopulmonary bypass time before the institution of circulatory support. Fortunately, pump dependency is rare, but when such occurs, staged transplantation can be carried out in those patients without contraindications to transplantation with reasonable results. However, caution may be advised in instituting circulatory support in patients older than 70 years. As might be expected, physiologic reserve is limited and the final outcome, less than desired. Future studies designed to clearly define those patient selection criteria and the associated variables that might allow for optimal timing of the institution of circulatory support are needed.

Circulatory Support in Conjunction With Cardiac Transplantation

Approximately one-fifth to one-third of all potential cardiac transplant recipients die before a donor organ is located. Furthermore, cardiac complications including inadequate donor organ preservation, acute rejection, and right-sided failure account for a large percentage of the early deaths after transplantation. With these in mind, the database in regard to the use of circulatory support in conjunction with transplantation at present consists of 66 reporting centers. Thirty-two of the centers are in the United States and 34 are outside the continental US. Demographically, there were 544 implants reported with 81% being in male patients with a mean age of 44 years.

Nineteen percent of the implants were in female patients, who were somewhat younger than their male counterparts, averaging 35 years of age. The marked male predominance was likely related to the large number of potential cardiac recipients with ischemic cardiomyopathy. The age distribution for circulatory support in conjunction with heart transplantation obviously parallels that seen in those individuals undergoing isolated cardiac transplantation. However, the best results in terms of the highest percent of patients receiving transplants and then subsequently being discharged occurs at the younger end of the age spectrum, with 80% receiving transplants and 81% of those receiving transplants surviving, and the worst results at the older end of the age spectrum, being a 50-50 proposition. A trend was present. However, the small sample size precluded statistical significance.

The indications for mechanical circulatory support were hemodynamic deterioration before transplantation in 436 patients, acute rejection in 40 patients, and postcardiotomy cardiogenic shock not considered related to acute rejection in 68 patients. In the 40 patients treated with circulatory support during rejection, only 23 (58%) underwent a second transplantation and 8 of the 23 patients (35%) ultimately were discharged from the hospital. This was an absolute salvage rate of about 20%. The 68 patients suffering from posttransplantation cardiogenic shock not related to rejection considered potentially reversible were presented for interest, but were not included in the subsequent analysis because myocardial recovery was anticipated or intended. The weaning rate of 29% was significantly lower than what has been reported in postcardiotomy shock after nontransplant procedures, which is 45% to 50%. However, the probability of being discharged from the hospital after device weaning was about two-thirds, which is a bit higher than the 50% or so reported in other postcardiotomy cardiogenic shock syndromes. Therefore, the absolute salvage rate was about 19%. This was statistically equal to that seen with postcardiotomy cardiogenic shock after other types of procedures.

The duration of circulatory support in these patients was quite variable, and underscores the necessity of the devices used in conjunction with transplantation to provide safe and reliable assistance over a wide range of times (range, 0 to 438 days). There was absolutely no statistical difference in the duration of support based on the type of device, ie, ventricular assist device versus total artificial heart. Interestingly, the experience failed to show that shorter durations of circulatory support are associated with a more favorable outcome. There was no difference statistically between those patients who did not undergo transplantation, the patients who underwent transplantation and died, and those who underwent transplantation and were subsequently discharged from the hospital.

The overall results of circulatory support by device type are depicted in Table 2. Of the 476 patients, 122 received isolated left ventricular support. Approximately 71% of those patients went on to subsequent transplantation, and 87% of those patients were then discharged from the

Table 2. Overall Results of Circulatory Support by Device Type

Device	No. of Patients	Transplanted	Discharged
RVAD	4	1 (25.0%)	1 (100%)
LVAD	122	87 (71.3%)	76 (87.4%) ^a
BVAD	161	105 (65.2%)	73 (69.5%) ^b
TAH	189	135 (71.4%)	67 (49.6%) ^c
Total	476	328 (68.9%)	217 (66.2%)

^{a-c} Fisher's exact two-tailed test: ^a LVAD versus BVAD, $p = 0.003$; ^b BVAD versus TAH, $p = 0.002$; ^c LVAD versus TAH, $p = 0.000$.

BVAD = biventricular assist device; LVAD = left ventricular assist device; RVAD = right ventricular assist device; TAH = total artificial heart.

hospital. One hundred sixty-one of the total patients were managed with biventricular paracorporeal assist devices and 65% of those underwent transplantation. Seventy-three of the 105 patients, or about 70%, were then discharged from the hospital. One hundred eighty-nine patients received pneumatically driven total artificial hearts, 71% underwent transplantation, and nearly 50% of those patients were then discharged from the hospital. The rates of transplantation were statistically equal regardless of the type of support employed. However, if one compared the outcome based on whether a patient received a total artificial heart or a ventricular assist device, there was a highly statistically significant difference with the best outcome seen with univentricular support, then biventricular paracorporeal support, and least favorable with the total artificial heart. The rates of subsequent transplantation, as well as hospital discharge, were identical in patients who received either a pneumatic assist device, an electrically activated device, or a centrifugally driven left ventricular assist device. However, those patients receiving centrifugal devices did fare less well overall, and if the sample size were a bit larger, it is conceivable that there would be statistical significance. The 30-day operative mortality with isolated orthotopic heart transplantation has remained at 10% to 12%. On the other hand, in those patients receiving transplants after device support, the mean operative mortality was about 18%. However, it was 9% for univentricular support, 18% for biventricular support, and 23% for total artificial hearts. The differences were highly significant between the ventricular assist devices and the total artificial heart. However, this did not reach statistical significance between the group of patients with biventricular support and the group with the total artificial heart. Kaplan-Meier survival estimates for all patients undergoing staged cardiac transplantation at 1 and 2 years after the procedures inclusive of the 30-day operative mortality were nearly 65%. This is in contrast to the nearly 80% actuarial survival in an isolated orthotopic cardiac transplant. However, when survival estimates were prepared for each type of mechanical support employed in conjunction with transplantation, the 1- and 2-year estimates for univentricular support were equivalent to isolated orthotopic

Table 3. Complications Precluding Heart Transplantation

Complication	Percentage of Patients (n = 148)
Bleeding	27% ^a
Biventricular failure	27% ^a
Renal failure	33% ^a
Respiratory failure	27% ^a
Infection	24% ^a
Multiorgan failure	15% ^a

^a Univariate predictor of not receiving a subsequent transplant.

cardiac transplantation at about 86% and 83%, respectively. Statistical analysis would bear out highly significant differences, with the best results obtained with univentricular support, then biventricular, and the least favorable with a total artificial heart.

The complications precluding transplantation after establishing circulatory support are listed in Table 3. Many of the patients suffered more than one complication. However, each of the listed complications was a univariate predictor of not receiving a subsequent transplant. Stepwise logistic regression analysis indicated in decreasing order of importance that bleeding, neurologic events, and biventricular and renal failure had a significant negative effect on future transplantation. The causes of 30-day mortality in these patients after staged transplantation indicated any patient may have had more than one factor. Univariate analysis indicated that bleeding, renal

failure, persistent respiratory failure, infection, and rejection negatively affected hospital discharge. Multivariate analysis indicated that bleeding, infection, and renal failure were the most important predictors of hospital death after staged transplantation. The causes of death after 30 days parallel those of the general isolated cardiac transplant population.

In conclusion, it would seem these results in the bridge-to-transplantation application are quite encouraging where support is instituted for hemodynamic instability and immediate donor organ unavailability. Nearly three-quarters of the patients will undergo subsequent transplantation when the initial support is univentricular and with an electric or pulsatile pneumatic device. Furthermore, in patients who receive transplants 30-day mortality and long-term survival are nearly equivalent to those in patients having isolated orthotopic cardiac transplantation. Certainly, we will continue to learn many important patient and device selection lessons, and only ongoing, careful clinical trials will improve the rates of successful transplantation. Ideally, it would be advantageous to be able to prospectively identify those patients requiring only univentricular support. It is likely that this information derived from staged cardiac transplantation will also have an impact on the future clinical trials slated for chronic totally implanted devices.

We gratefully acknowledge the assistance of Yvonne Matthews, MA, who provided statistical analysis. We are also indebted to the voluntary participants of the Combined Registry for their continuing support in providing patient data.

Current Expectations in Dynamic Cardiomyoplasty

Luiz Felipe P. Moreira, MD, Edimar A. Bocchi, MD, Noedir A. G. Stolf, MD, Fúlvio Pileggi, MD, and Adib D. Jatene, MD

Instituto do Coração da Faculdade de Medicina da Universidade de São Paulo, São Paulo, Brazil

Dynamic cardiomyoplasty has been evaluated in the treatment of severe cardiomyopathies. This report outlines the results of this procedure in 21 patients with dilated or ischemic cardiomyopathy who were in New York Heart Association class III or IV before operation. There were no operative deaths. Patients were followed up for a mean of 17.6 months. Eight patients died during late follow-up, and actuarial survival rates were 73.2% at 1 year and 65.9% at 2 years of follow-up. Functional class improvement was documented in the surviving patients. Furthermore, significant improvement in left ventricular

function was demonstrated by radioisotopic angiography and by heart catheterization for more than 2 years after the operation. These studies documented that left ventricular ejection fraction increased as a result of global improvement in regional wall motion. Absence of clinical and hemodynamic improvement after cardiomyoplasty seems to be related to muscle flap ischemic compromise, whereas the patient's condition before operation seems to influence the long-term outcome of cardiomyoplasty.

(*Ann Thorac Surg* 1993;55:299-303)

Dynamic cardiomyoplasty has evolved rapidly in the last 6 years. After the pioneering efforts of the Broussais Hospital group, in Paris, this surgical procedure has been evaluated throughout Europe, South America, Canada, and the United States. It has been indicated to partially replace or reinforce the heart muscle in the treatment of left ventricular (LV) tumors or aneurysms [1-6] and in patients with severe cardiomyopathies [2, 4-9].

Initial outcomes demonstrated the improvement of LV function and reversion of congestive heart failure in patients with dilated cardiomyopathies after cardiomyoplasty [8, 9]. This technique has also been reported in a heterogeneous group of patients and associated with other procedures [1-6] and devices that provide different muscle stimulation [6, 7], making difficult the analysis of cardiomyoplasty benefits.

The purpose of this report is to outline the results of dynamic cardiomyoplasty in the treatment of patients with advanced heart failure due to dilated or ischemic cardiomyopathy at the Heart Institute of São Paulo University Medical School. Present trends in this field will also be reviewed.

Patients and Methods

Patient Selection

Patients currently selected for cardiomyoplasty are those at high risk of dying within 1 year due to severe cardiomyopathies, which does not essentially differ from heart transplantation criteria [10]. Nevertheless, these patients need to be stable enough on medical therapy to withstand a waiting period of 6 to 8 weeks before effective skeletal

muscle flap adaptation. Serious mitral regurgitation, medically untreated arrhythmias, and major enlargement of the left ventricle are also considered contraindications to this procedure.

Dynamic cardiomyoplasty was performed in 21 patients at our institution between May 1988 and September 1991. Fifteen patients were in New York Heart Association (NYHA) class III and 6 were in class IV despite the use of maximal conventional medical therapy. The cause of heart failure was idiopathic dilated cardiomyopathy in 17, Chagas' disease cardiomyopathy in 2, and ischemic cardiomyopathy in 2 patients. Patients' ages ranged from 16 to 57 years (mean, 43.2 years), and 18 patients were male. Preoperative laboratory data are summarized in Table 1. Three patients had chronic atrial fibrillation and 10 had nonsustained ventricular tachycardia episodes documented by Holter recordings. Cardiac catheterization showed compromise of coronary arteries in 2 patients, mild mitral insufficiency in 11, and moderate mitral insufficiency in 4. Standard spirometric study documented mild restrictive compromise of the ventilatory function in 16 patients. All patients signed a special informed consent under the Scientific Committee of the Heart Institute of São Paulo University Medical School.

Surgical Procedure

Dynamic cardiomyoplasty was performed by means of two separate incisions: a lateral approach for muscle flap dissection and a median sternotomy for cardiac access. Dissection and transposition of left latissimus dorsi muscle followed the technique described by Chachques, Grandjean, and Carpentier [11]. The muscle flap was wrapped around the ventricular surfaces as previously described [8, 9], providing a left posterior cardiocostal wrapping [12]. Two intramuscular pacing electrodes (Medtronic SP 5528, Maastricht, the Netherlands) were implanted in the skeletal muscle graft, and an epimyocar-

Presented at the Circulatory Support 1991 Symposium of The Society of Thoracic Surgeons, San Francisco, CA, Nov 16-17, 1991.

LV = left ventricular; RV = right ventricular.

dial sensing lead (Medtronic SP 5548) was placed in either the right or left ventricle. The Medtronic SP 1005 cardiomyostimulator was used for muscle flap stimulation. Further, 1 patient with ischemic cardiomyopathy underwent saphenous vein aortocoronary bypass grafting into the right coronary artery without cardiopulmonary bypass.

Electrical stimulation of skeletal muscle flap started 2 weeks after the operation, and a progressive muscle conditioning protocol was followed [13]. At the late postoperative period, muscle flap was paced in 1:1 mode with the heart rate. Pulse train stimulation was used with a burst frequency of 30 Hz and associated with supramaximal pulse amplitude values to avoid ineffective muscle flap contraction. The delay between the ventricular sensed event and the muscle burst was adjusted to provide an exact synchronization between muscle flap contraction and ventricular systole [8].

Follow-up Protocol

Patients were studied every 6 months after the operation by means of Doppler echocardiography, radioisotopic angiography, right heart catheterization, 24-hour Holter recordings, and cardiopulmonary exercise test, as previously published [8, 9].

Left ventricular catheterization was performed after 1 year of follow-up with the cardiomyostimulator on and turned off for at least 24 hours. Cineangiograms were recorded at right anterior oblique view. End-diastolic and end-systolic endocardial contours were analyzed by means of computer software. Left ventricular ejection fraction was calculated by the area-length method [14], and regional wall motion was quantified using the center line method [15].

Statistical Analysis

One-way analysis of variance and paired Student's *t* test were used to compare data before and after cardiomyo-

plasty and data obtained with the cardiomyostimulator turned on and off. Cumulative mortality rates over time were determined by the actuarial method, and differences between them were assessed by the log-rank test. A value of *p* less than 0.05 was considered significant. Laboratory data are presented as mean ± standard deviation, whereas survival rates are presented as mean ± standard error of the mean.

Results

Immediate Surgical Results

There were no operative deaths in this series. Dopamine or dobutamine and sodium nitroprusside were prophylactically used to maintain normal cardiac output during cardiomyoplasty and the first week after the operation.

Immediate postoperative course was in general uneventful. A transient period of multiple organ failure developed in 2 patients, 2 patients had atrial fibrillation or flutter, and 1 patient had pulmonary infection. In addition, left arm paresis was observed in 2 patients for 2 months after cardiomyoplasty.

Muscle flap ischemic compromise was monitored by variations in the serum level of creatine kinase, which showed a mean peak value of 984 ± 568 IU at 38 ± 18 hours of follow-up. Four patients had peak values of creatine kinase greater than 1,500 IU, among them the 2 patients in whom transitory multiple organ failure developed. One of these patients had absence of muscle flap contraction with maximal electrical stimulation and died of congestive heart failure 2 months after the operation. Latissimus dorsi normal fibers intermingled with areas of fibrosis were documented by microscopic study. Poor muscle flap contraction was observed under pulse train stimulation in the remaining 3 patients.

Eighteen patients completed the muscle conditioning protocol and were followed up from 4 to 41 months (mean, 20.1 ± 11.5 months). One patient remains in the muscle conditioning period and 1 patient died at 2 months of follow-up owing to severe pulmonary thromboembolism and infection.

Circulatory Function Evaluation

At 6 months of follow-up, radioisotopic angiography demonstrated that LV ejection fraction improved from 0.21 ± 0.04 to 0.25 ± 0.07 (*p* = 0.01). However, this variable did not change in the 3 patients with significant increases in creatine kinase level at the immediate postoperative period and in 1 patient with an LV internal diastolic diameter of 89 mm. There was no variation in right ventricular ejection fraction after the cardiomyoplasty (0.24 ± 0.06 versus 0.25 ± 0.07).

Left ventricular cineangiographic study, performed in 10 patients at 16 ± 4 months of follow-up, documented that ejection fraction increased in patients who survived long-term after cardiomyoplasty from 0.15 ± 0.08 to 0.31 ± 0.08 (*p* = 0.01). This improvement resulted from a global modification of LV wall motion as depicted in Figure 1. This study also showed a decrease in LV ejection

Fig 1. Left ventricular regional wall motion, obtained by end-diastolic and end-systolic contour traces, before and after dynamic cardiomyoplasty. The bar graph shows the percent increase in this variable in the anterobasal (AB), anterolateral (AL), apical (AP), diaphragmatic (D), and posterobasal (PB) regions in the postoperative period.

fraction to 0.23 ± 0.13 when the cardiomyostimulator was turned off for 24 hours ($p = 0.06$).

Right heart catheterization demonstrated that cardiac index increased from 1.76 ± 0.28 to 1.93 ± 0.3 L/min $\cdot$ m ^{2} at 6 months of follow-up ($p = 0.04$) and showed a significant improvement in global circulatory function, as documented by LV stroke work index and pulmonary wedge pressure variations (Fig 2). This hemodynamic improvement and LV ejection fraction increase persisted for 12 and 24 months after the cardiomyoplasty, as shown in Table 2.

Survival and Quality of Life

Six of the 18 patients who completed the muscle conditioning period and were followed up long-term died;

Fig 2. Left ventricular stroke work index and pulmonary wedge pressure variations from the preoperative period to the sixth month of cardiomyoplasty follow-up.

actuarial survival rates are depicted in Figure 3. The causes of death were progression of heart failure associated with pulmonary infection, cerebral vascular accident, or renal failure in 3 patients; pulmonary thromboembolism in 1 patient; and sudden death in 2 patients who died after the second year of follow-up. Progression of heart failure occurred in patients without postoperative improvement of LV function, whereas patients who died suddenly were under medical therapy for severe tachyarrhythmias.

Furthermore, patients operated on in NYHA class III had a survival rate of 86.1% at 1 year and at 2 years of follow-up, whereas actuarial survival rates for patients operated on in NYHA class IV were 50% and 33.3% at the same periods ($p = 0.02$).

Among the 12 surviving patients in long-term follow-up, 6 returned to NYHA class I, 5 are in class II, and 1 is in class III, some of them using fewer drugs or lower doses than they did in the preoperative period. Nine of these patients resumed their professional activities.

Comment

Improvement of LV function with dynamic cardiomyoplasty is documented in patients with dilated or ischemic cardiomyopathies. In these patients, LV ejection fraction increases as result of global improvement in regional wall

Table 2. Sequential Hemodynamic and Radioisotopic Data^a

Variable	Preoperative	Follow-up			p Value
		6 months	12 months	24 months

motion, and the mechanism of action seems to be essentially the augmentation of systolic function through the action of synchronized skeletal muscle contraction. This mechanism has been widely demonstrated in experimental reports [13, 16-19]. Furthermore, this concept was confirmed to some extent by the LV ejection fraction decrease when the cardiomyostimulator was turned off in the late follow-up period in this study.

Although LV ejection fraction increase and cardiac output augmentation at rest seems to be modest in patients with severe cardiomyopathies, cardiomyoplasty's impact on circulatory function may be better evaluated by its significant influence on LV stroke work and pulmonary pressures. In addition, more evident changes in cardiac output and global circulatory function have been clinically documented, especially during exercise [20].

Besides these hemodynamic benefits, dynamic cardiomyoplasty may also influence the mechanical properties of the failing heart itself. Reduction in LV wall stress was demonstrated after this surgical procedure in a canine model of dilated cardiomyopathy [19], indicating that cardiomyoplasty may decrease myocardial oxygen consumption as previously suggested [9]. Accordingly, in a dilated, failing left ventricle, the afterload matching and the myocardial contractility may be partially restored and slow progression of the underlying cardiomyopathy may result from this mechanism [21]. The maintenance of LV ejection fraction and hemodynamic improvement for more than 2 years after the operation in the present report indicates that this may occur clinically. Also, cardiomyoplasty's influence on LV diastolic compromise was documented by Doppler echocardiography, indicating partial recovery of myocardial compliance at late follow-up [22].

Cardiomyoplasty benefits may be influenced by technical aspects and by skeletal muscle flap response to electrical stimulation. Better LV ejection fraction improvement has been documented in patients with lesser LV end-diastolic dimensions, which is in general agreement with Laplace's law [8]. Furthermore, absence of LV ejec-

tion fraction increment occurred in patients with important muscle flap ischemic compromise after the operation. This event demonstrates the importance of skeletal muscle contractile state for cardiomyoplasty effectiveness and shows the necessity to preserve normal muscle flap perfusion in the immediate postoperative period. The optimal orientation of muscle fiber direction [18], the extent of the wrap around the heart [22], and the optimal stimulation protocols for transformation and assist [8, 13] remain controversial.

Improvement in functional class and exercise capacity has been demonstrated by overall clinical experience with dynamic cardiomyoplasty [2-4, 6, 7, 23]. In addition, cardiomyoplasty's influence on the survival of patients with advanced heart failure has been suggested by several authors [2, 4, 9, 23].

Reversion of congestive heart failure and a significant increase in maximal oxygen consumption during treadmill test were documented by our group for at least 2 years after cardiomyoplasty in patients with dilated cardiomyopathies [22, 23]. Furthermore, this surgical procedure may be performed in these patients with low operative mortality. Long-term survival improvement with cardiomyoplasty was also demonstrated in patients with dilated cardiomyopathies, comparing cardiomyoplasty results with the natural history of this disease under medical therapy [23]. Patients operated in functional class IV, however, exhibited a significantly higher mortality than those operated on in class III, suggesting that the patient's condition before the operation plays an important role in the long-term outcome.

Progression of heart failure was an important cause of death after cardiomyoplasty in patients with severe cardiomyopathies. Nevertheless, it was related to patient selection criteria or to technical limitations, which may be improved. There were also deaths caused by pulmonary thromboembolism and deaths that occurred suddenly in patients with documented tachyarrhythmias. These complications are probably not affected by cardiomyoplasty itself. However, they frequently occur in patients with advanced heart failure and still need effective means to be precluded [24]. The deleterious effects of ventricular arrhythmias on cardiomyoplasty results were also reported by other authors [7, 25]. Furthermore, active myocarditis [26] and right ventricular function compromise in patients with ischemic cardiomyopathy [6] have also been related to cardiomyoplasty mortality.

Interpretation of the current clinical experience with dynamic cardiomyoplasty is limited. This surgical procedure improves LV function, reverses congestive heart failure, and seems to improve long-term survival of patients with severe cardiomyopathies. Nevertheless, the improvement of LV function with cardiomyoplasty may be limited by technical aspects and by the possibility of muscle flap damage. Also, cardiomyopathy's steady evolution after cardiomyoplasty may be influenced by the patient's condition before operation, suggesting that this procedure should be better indicated in patients with mild or moderate heart failure.

Emergency Resuscitation Using Portable Extracorporeal Membrane Oxygenation

Walter P. Dembitsky, MD, Ricardo J. Moreno-Cabral, MD, Robert M. Adamson, MD, and Pat O. Daily, MD

Sharp Memorial Hospital, San Diego, California

Manual cardiopulmonary resuscitation is currently the standard treatment for cardiac arrest patients both in and out of the hospital. Accumulated experimental and anecdotal clinical evidence suggests enhanced survival in patients with extreme circulatory decompensation who have been emergently supported with portable cardiopulmonary bypass. Long-term survival is possible even when application is delayed, but early institution of support after cardiac arrest in selected patients offers the best survival advantages. In our hospital this has been achieved by training a team of in-house personnel to

emergently prepare, apply, and temporarily manage cardiopulmonary bypass until personnel with greater specialty training arrive. Machinery needed to perform emergency cardiopulmonary bypass is currently available in all hospitals with open heart surgery programs. Simple support is often therapeutic but can also serve as a bridge to definitive diagnostic and other therapeutic procedures. Commercial units are becoming more biocompatible and easier to use, making both wider application and more prolonged support likely in the future.

(*Ann Thorac Surg* 1993;55:304-9)

The first reported experience with closed chest methods of augmenting circulation was by Boehm in 1878 [1], working with arrested cats. It was not until 1947 that Gurvich and Yuniev [2] were able to effectively cardiovert experimentally induced ventricular fibrillation. They found that cardioversion was not possible if arrest lasted more than 1.5 minutes. However, this interval could be extended to 8 minutes if external compressions of the chest were used. Working on this background, Kouwenhoven and associates [3] described the technique of applying their alternating current defibrillator to patients undergoing closed chest cardiopulmonary resuscitation (CPR) in 1960. Cardiopulmonary resuscitation has subsequently become standard therapy for cardiac arrest patients, whether in or out of the hospital.

The physiology of extreme circulatory decompensation has been evaluated both experimentally and clinically [4, 5]. During cardiac arrest with closed chest massage, cardiac output falls to approximately 20% of normal. Systolic arterial pressure is maintained, but mean arterial pressure falls below the average level of approximately 60 mm Hg because of low diastolic pressures. Venous pressure gradually rises above the normal level of 5 mm Hg to as high as 20 to 30 mm Hg. Rising venous pressure and falling mean arterial pressure gradually create an inadequate peripheral tissue perfusion gradient, which, coupled with low cardiac output, results in multi-

ple organ failure. Because of the cumulative nature of injuries incurred during CPR, it is not surprising that during experimental or clinical cardiac arrest, survival is extremely rare if CPR lasts longer than 30 minutes [6, 7].

Abnormal circulatory dynamics can be rapidly corrected by the peripheral application of venoarterial bypass using an oxygenator. During cardiopulmonary bypass, the central venous pressure falls to desirably low levels as mean arterial pressure and cardiac output rise. As seen in Figure 1, application of peripheral bypass establishes the circulatory milieu necessary for peripheral organ sustenance and maintenance. In the detailed work of Levine and colleagues [7], advantages of peripherally applied cardiopulmonary bypass for resuscitating animals following cardiac arrest was demonstrated. The results are summarized in Figure 2. After 30 minutes of cardiac arrest with standard cardiopulmonary resuscitation, a control group of animals was subjected to advanced life support, which included the application of cardiostimulant drugs. The test group was placed on peripheral cardiopulmonary support. All animals receiving peripheral cardiopulmonary support versus 50% of the animals on advanced life support were easily cardioverted. At 24 hours, 7 of 10 animals on peripheral cardiopulmonary support survived with normal central nervous system function compared with 3 of 10 animals receiving advanced life support, 2 of which had normal cerebral function. Thus it appears that application of cardiopulmonary bypass to arrested animals, even after 30 minutes of CPR, can result in improved survival as compared with CPR with advanced life support alone. Clinical experiences suggest that the same is true in humans [8-11].

Presented at the Circulatory Support 1991 Symposium of The Society of Thoracic Surgeons, San Francisco, CA, Nov 16-17, 1991.

Address reprint requests to Dr Dembitsky, Sharp Memorial Hospital, 7901 Frost St, San Diego, CA 92123.

Fig 1. The hemodynamics produced during cardiopulmonary resuscitation (CPR) are summarized on the left. The cardiac index (CI) is usually less than $1 \text{ L} \cdot \text{min}^{-1} \cdot \text{m}^{-2}$. The central venous pressure (CVP) rises as the mean arterial pressure (MAP) falls. This produces a marginal tissue perfusion gradient (ΔP). Introduction of peripherally applied venoarterial (VA) extracorporeal membrane oxygenation (ECMO) immediately creates a satisfactory cardiac index and improves the peripheral tissue perfusion gradient.

Technology Available for Portable Extracorporeal Membrane Oxygenation

Following the work of Stephen Phillips and co-workers [12], a variety of companies (Bard Cardiopulmonary Division, Tewksbury, MA; Sarns 3M Health Care, Ann Arbor, MI; Medtronic, Inc, Minneapolis, MN) have developed commercially available portable cardiopulmonary bypass systems that can be percutaneously applied. All are relatively simple to prime and, in fact, some experimental work has now been done with systems that remain permanently primed. The most encouraging recent development has been the clinical use of heparin-coated peripheral bypass circuits. These coated surfaces offer two advantages. First, they are minimally thrombogenic, and second, they are known to diminish the activation of blood components contacting them. The diminished activation of the complement cascade, preserved platelet

Fig 2. Experimental evidence demonstrating improved survival after 30 minutes of cardiac arrest with cardiopulmonary resuscitation in animals supported by peripherally applied extracorporeal membrane oxygenation and venoarterial bypass (CPS) when compared with animals receiving continued cardiopulmonary resuscitation with the addition of advanced cardiac life support technique (CPR-ACLS). (CNS = central nervous system.) (Reprinted from Levine R, Gorayeb M, Safar P, Abramson N, Stezoski W, Kelsey S. Cardiopulmonary bypass after cardiac arrest and prolonged closed-chest CPR in dogs. *Ann Emerg Med* 1987;116:620-7, by permission.)

levels, normal patient prothrombin time, partial thromboplastin time, and bleeding times associated with the use of these circuits have permitted their application in situations where hemorrhage is either an active or a potentially active problem. They have successfully supported patients with multiple trauma and patients requiring major operations. An unproven possible advantage of using coated circuits for emergency cardiopulmonary bypass, where the usual precoating of a circuit with albumin is impractical, is that the more biocompatible surfaces may reduce the incidence of multiple systems injury in emergently supported patients with shock.

Surgical Techniques

Venous Cannulation

Because the portable systems do not use a reservoir and therefore aspirate blood directly from the heart, higher flows through relatively small-bore cannulas can be achieved. This is in contrast to conventional cardiopulmonary bypass, where relatively large-bore venous cannulas are used in a gravity drainage system to fill a reservoir. Twenty French venous cannulas can be percutaneously positioned in the right atrium, either through the femoral vein or through the right internal jugular vein. In our own experience, emergency percutaneous femoral cannulation has occasionally resulted in retroperitoneal venous disruption requiring circulatory arrest for the repair and ultimate survival of 1 patient. Retroperitoneal perforation can be averted by the use of internal jugular vein as a percutaneous right atrial access site. Repair is simpler in the rare patient with internal jugular vein injury. Furthermore, venous flows are apt to be higher because of the shorter catheters required for more certain direct right atrial access.

Arterial Cannulation

Arterial blood is returned to the femoral artery. Because patients in cardiac arrest generally suffer the arrest because of cardiac dysfunction, not pulmonary dysfunction, it is not necessary to direct the arterial blood flow back to the supravalvular region. The cannulas can be placed percutaneously using a Seldinger technique with progressive dilation of the artery or, especially in arrested patients, by cut-down usually combined with the modified Seldinger technique. Rapid peripheral arterial access may not be possible in patients with aortoiliac occlusive disease. Even when cannulated, obstructive disease in some patients does not permit adequate retrograde perfusion. In occasional patients the small, high-flow jet from the arterial cannula can dislodge atheromatous excrescences and produce systemic arterial embolization. Rarely peripheral cannulation can result in aortic dissection. In patients in whom prolonged perfusion is required, it may occasionally be necessary to cannulate the peripheral femoral artery and vein to prevent leg ischemia and venous stasis.

Oxygenators

The oxygenators that are currently most commonly used for emergency cardiopulmonary bypass are those using

"hollow fiber" membranes. Because the fibers are not true membranes but are microporous, they tend to progressively exude plasma after 12 to 36 hours of use. In the future, diminishing pore size as well as the potential addition of silicone coat to one side of the fiber will eliminate plasma leakage. Available oxygenators with heparin-coated fibers are minimally thrombogenic; however, all are currently constructed in biologically improbable ways, which create thrombosis in areas of stasis. This problem makes the use of some circulating heparin desirable.

Pumps

Two types of pumps are used in emergency cardiopulmonary resuscitation with portable bypass units. The most widely applied types are the nonocclusive, pressure-limited centrifugal pumps. Currently, the most frequently used is the Bio-Medicus pump, followed by the Sarns pump and then the St. Jude pump. All three are minimally hemolytic, although over long-term use, they appear to be mildly thrombogenic. The advantage that they offer for emergency cardiopulmonary bypass is that the centrifugal pumps are pressure-limited and, therefore, any abrupt occlusions of inflow and outflow cannulas are unlikely to result in either aspiration of air or disruption of lines. Their use in long-term support is less desirable because of their thrombogenicity.

The second type of pump that can be used for peripheral resuscitating bypass units is the common roller pump. These pumps are not pressure-limited and consequently can develop extremely high venous inflow and arterial outflow pressures. This can make emergency use of these pumps somewhat cumbersome if patient mobility is important. For support lasting more than 1 or 2 days, these pumps become more advantageous.

Conduct of Emergency Cardiopulmonary Bypass

After vascular access has been established, cardiopulmonary bypass is begun and conducted in the usual way with a few exceptions. Because peripherally applied cardiopulmonary bypass usually does not capture all venous return to the heart, some blood may continue to flow through the lungs, into the left ventricle, and, subsequently, to the coronary arteries and cerebral circulation. Thus, continued high endotracheal oxygen insufflation is necessary to prevent desaturated blood from being ejected from the left ventricle. Distention resulting from varying amounts of aortic insufficiency and bronchial flow filling the arrested left heart can be minimized by prompt defibrillation of the heart. Cardioversion is made easier by collapsing the engorged left ventricle using simple sternal compression. Experimental left ventricular decompression during peripheral cardiopulmonary bypass in animals with ventricular fibrillation has been achieved by placing a helical coil across the pulmonary valve to render it incompetent and permit left ventricular decompression [13]. Clinical use of this technique had not been reported. In our own experience, the actual occurrence of left ventricular distention has been minimal. It can be monitored using transthoracic or transesophageal echocardiog-

raphy, or with a pulmonary artery pressure monitoring catheter (pulmonary artery pressure during ventricular fibrillation is equal to the left intraventricular pressure). After the initiation of full cardiopulmonary bypass, arrested patients may suddenly awaken and become combative and require immediate sedation or muscle paralysis.

Because emergency cardiopulmonary bypass is often established in patients who are not fully monitored, the adequacy of perfusion must initially be determined by clinical examination. Temperature of the upper extremities is assessed. The arterial pressure is determined initially using a Doppler apparatus with pressure cuffs and later using arterial monitoring lines. The arterial and venous cardiopulmonary bypass access lines are examined to roughly determine the arterial-venous oxygen difference. If both arterial and venous catheters are desaturated, blood flow to the oxygenator is insufficient. If both are fully saturated, venovenous bypass must be ruled out. Alternatively, in some patients after cardiac arrest with prolonged CPR, peripheral oxygen extraction may be so low that the arteriovenous oxygen difference, even with low flows, is minimal. This usually denotes peripheral organ death and a poor prognosis.

During cardiopulmonary bypass in patients with cardiac arrest due to acute coronary occlusion, it is theoretically advantageous to reduce the systemic temperature to prolong the "safe" ischemic time for the injured heart. Some commercially available emergency cardiopulmonary bypass units have cooling as well as heating units incorporated into their circuits.

Current Results of Clinical Trials Using Portable Emergency Cardiopulmonary Bypass Systems

On the 31st anniversary of the discovery and clinical application of CPR [14], reported results have been less encouraging than the initial experience seemed to project. In two recent reviews of the literature, the current results of CPR on in-hospital patients have been reviewed [6, 15-17]. Approximately 50% of the patients can be resuscitated initially, but only 10% of the patients ultimately leave the hospital. In our experience at Sharp Memorial Hospital in San Diego, the discharge rate had been somewhat higher. Over a 1-year period, approximately 65% (91/140) of 140 arrested patients were resuscitated. Twenty-six percent (23/91) of those patients were discharged. The average duration of CPR was approximately 22 minutes. Many have questioned how widely CPR should actually be applied in the hospital setting. The procedure is expensive, and in those with little hope of long-term survival, it may be inhumane and even undesirable. Each institution must address the patient selection issues individually. Our results of in-hospital CPR have improved primarily by the more judicious application of the technique.

Based on the experimental evidence available, one would expect enhanced survival in patients if, after CPR, they were supported early by judiciously applied peripheral extracorporeal bypass circuits. Control studies evalu-

Fig 3. Summary of 1991 Registry data on 116 patients with witnessed arrests. Even with cardiopulmonary resuscitation (CPR) lasting more than 30 minutes, prolonged survival is possible.

ating the technique are unlikely to be created in the near future. The only evidence available is the anecdotal clinical reports now appearing in the literature. Data from the 1991 National Cardiopulmonary Support Registry for emergency applications have been recently reported [18]. The Registry collected information from 17 different institutions treating 187 patients using emergency cardiopulmonary bypass. Forty of 187 patients ultimately survived, for an overall survival rate of 21%. Of the 187 patients, 75% (140/187) had diagnostic and therapeutic interventions performed while on cardiopulmonary bypass. These procedures included pulmonary embolectomy, pulmonary artery bypass grafting, and pulmonary and arterial angiography, as well as angioplasty. When one compares the survivors with the nonsurvivors, approximately 77% (31/40) of the survivors had a therapeutic intervention while being supported, whereas only half (73/147) of the nonsurvivors did. This suggests that the application of cardiopulmonary bypass allows the patient to be transferred to more advanced forms of diagnostic and therapeutic intervention, which might enhance his or her survival. In Figure 3, the results of witnessed arrests in 116 patients reported in the Registry are seen. Although differences between the three groups of arrest times depicted are not statistically significant, it is clear that survival, even after 221 minutes of cardiac arrest, is possible using peripherally applied ECMO.

Because the Registry data represent the broad application of a technology in multiple institutions, some insight can be gained by looking at single-institution experiences. At the 37th Annual Meeting of the American Society for Artificial Internal Organs, Dr Charles Moore [19] reported experience with 67 patients with a 30-day survival rate of 31%. Dr Mooney and associates [8] reported a 64% survival in 11 patients (7/11) undergoing emergency cardiopulmonary bypass. When we analyzed data from our initial reported series and divided the patients into early and late experience, the long-term survival of our most recent cohort was approximately 30% (7/20), compared with the early long-term survival of only 10% (2/20). Our improved survival is the result of better patient selection

as well as an emphasis on early institution of emergency ECMO.

We have created an emergency ECMO team that comprises informed physicians, nurses, and perfusionists. The training for the team includes an initial didactic session describing the physiology of the technology as it is applied to the patient, as well as the potential complications of the devices. Direct, hands-on, "wet lab" experience is also provided during the initial training session. After the introductory training, designated nurses in the hospital carry beepers. They are readily available to bring resuscitative units to the bedside of arrested patients, prime the pump, and begin cardiopulmonary bypass. These nurses participate in laboratory training every 2 months and are able to prime the pump and commence cardiopulmonary bypass within 10 minutes of notification.

Careful attention must be paid to the hospital deployment plan for the use of this potentially lifesaving technology. This must be begun at the bedside by the physician attending the arrested patient. The physician must decide almost immediately if the arrested patient is a good long-term survival candidate. Once that decision has been made, a call for the cardiopulmonary bypass unit, which he or she may or may not ultimately use, is issued. In our hospital, perfusionist and cardiothoracic surgeon are notified as soon as the nurse who brings the unit to the bedside is notified. Cannulas are placed at the bedside by the physician in attendance. Physicians who are capable of percutaneously placing catheters for use as dialysis access conduits in patients are also capable of placing cannulas for extracorporeal circulation. In precarious patients, it is prudent to place percutaneous access lines in the femoral artery, internal jugular vein, or common femoral vein before cardiac arrest. This facilitates the later application of larger bore cannulas after cardiopulmonary arrest, when finding an arterial pulse can be difficult. Cannulas are placed, and the patient is attached to the perfusion unit, which is activated by the nurses. The patient is supported, and the ultimate disposition is decided by the physician in attendance.

Complications

Complications unique to emergency peripherally applied cardiopulmonary bypass are largely related to the emergency vascular access sites. In our reported experience [9], vascular access was not possible in approximately 10% of patients (2/38). In Dr Moore's experience 2 of 53 patients could not be cannulated (as reported at the 37th Annual Meeting of the American Society for Artificial Internal Organs). In the multiinstitutional experience, 26 of 187 patients (14%) experienced technical problems with cannulations, which are summarized in Table 1. For the 135 patients who died, the major organ dysfunctions contributing to death are seen in Table 2. It is not possible to determine whether these maladies were antecedent to or the result of emergency cardiopulmonary bypass. Probably some resulted from delayed institution of cardiopulmonary bypass after prolonged CPR. It is possible that the

introduction of emergency hemodilutional cardiopulmonary bypass into patients undergoing prolonged CPR may in some way predispose these patients to multiple organ failure syndrome. The Elective Supported Angioplasty Register reported its multiinstitutional experience with the first 100 patients undergoing supported angioplasty. This experience represents a best-case scenario for the introduction of peripheral percutaneous cardiopulmonary bypass in the relatively controlled environment of the cardiac catheterization laboratory [20]. The reported morbidity is seen in Table 3. Understandably, local cannulation problems are less frequent and multisystem organ failure does not appear. A few cases that may be the result of retrograde embolization (cerebrovascular accident, renal failure, small bowel infarction) do appear and may reflect the incidence of this problem in a large population of patients likely to be the recipients of emergency resuscitative cardiopulmonary bypass.

Conclusion

It appears that early, judicious application of emergency cardiopulmonary bypass to properly selected patients in cardiac arrest offers a survival advantage. The devices should be used only in patients with witnessed arrests, with the possible exception of arrested victims suffering from hypothermia. Technology to miniaturize the cir-

cuitry to make it more biocompatible and less expensive is available. Whether or not the technology will become distributed to the hands of those using and needing it will depend on the economic pressures of supply and demand. In the meantime, the equipment that is readily available today can be successfully used for patient care only when it is combined with an organized, carefully considered team approach.

Pharmacological Bridge to Cardiac Transplantation: Current Limitations

Daniel Y. Loisançe, MD, Philippe H. Deleuze, MD, Rémi Houel, MD, Christophe Benvenuti, MD, Adel El Sayed, MD, Jean-Philippe Mazzucotelli, MD, Antoine Tarral, MD, Jean-Pierre Saal, MD, and Jean-Paul Cachera, MD

Addition of intravenous enoximone to sympathomimetic agents permits a rapid and drastic improvement in the clinical and hemodynamical condition of patients in cardiogenic shock referred for a mechanical bridge to transplantation. The present experience, based on the management of 52 patients, permits us to point out the

current limitations of this pharmacological bridge: the rate of sudden death, the incompleteness of the physical rehabilitation of the patients, and the vanishing effect of intravenous enoximone.

(Ann Thorac Surg 1993;55:310-3)

A mechanical bridge has been proposed for patients in cardiogenic shock who are unresponsive to optimal medical therapy based on sympathomimetic agents. These patients may be patients whose condition is deteriorating while they are waiting on the transplant list or those referred acutely for an immediate transplantation. The addition to the widely used medical therapy of intravenous enoximone has been shown to improve immediate survival [1] and to reduce the need of mechanical circulatory support and, consequently, the cost of the management of such patients [2]. The present pharmacological strategy gives time for a reevaluation of the indications for the transplantation, thus permitting the saving of grafts. It permits the discovery in a less emotional context of hidden contraindications. It also gives an alternative to those patients, refused for transplantation, who will otherwise die.

The pharmacological bridge strategy, consequently, satisfies both the patient's instinct to stay alive and, at the same time, society's concern about the cost and cost-effectiveness of health care in acutely ill patients.

The present work, which is based on the experience obtained in 52 patients, points out the current limitations of the pharmacological bridge strategy.

Clinical Material

The 52 patients considered for the study entered the protocol from January 1986 to September 1991. Four were previously selected for cardiac transplantation (HTx) and were referred because of acute deterioration while waiting on the transplant list. Forty-eight were acute patients referred from various intensive care units in France. Mean

age was 51 years (range, 22 to 64 years). There were 46 men and 6 women. Duration of the period of sympathomimetic support before the start of enoximone therapy was 15 hours, ranging from 2 hours to 4 days. Cause of the cardiopathy was ischemic in 22, including 15 with acute myocardial infarction, valvular in 2, dilated cardiomyopathy in 25, acute rejection in 1, and acute viral myopathy in 2.

The detailed protocol has been previously published [1] and is illustrated schematically in Figure 1. The criteria for inclusion in the protocol included clinical evidence of cardiogenic shock, confirmed by hemodynamic data (cardiac index $< 2 \text{ L} \cdot \text{min}^{-1} \cdot \text{m}^{-2}$, mean aortic pressure $< 75 \text{ mm Hg}$, pulmonary capillary wedge pressure $> 25 \text{ mm Hg}$), obtained under maximal sympathomimetic support and optimal medical management. Only patients with no contraindication to transplantation (age > 65 years, diabetic, cancer, infection) were included. Indication for mechanical circulatory support was the lack of improvement in hemodynamical indices and rhythm complications.

Results

After the first intravenous enoximone injection the clinical and hemodynamical situation (Table 1) was dramatically improved in 44 patients. The most spectacular change was the increase in urine output, even in patients previously anuric. In 8 patients, no improvement was observed within the first 30 minutes of observation. In addition, rhythm troubles occurred, with ventricular tachycardia and fibrillation in 3 patients. Conventional resuscitation maneuvers including rapid institution of cardiopulmonary bypass (in 2) were successful in all. These 8 patients were eligible for the mechanical bridge strategy. In the 44 patients responsive to enoximone, enoximone bolus was repeated every 8 hours.

Fig 1. Schematic representation of the protocol.

Mechanical Bridge Patients

The type of mechanical circulatory support system that was used was a Jarvik 7-70 in 3 patients, a Symbion left ventricular assist device in 1 patient, biventricular assist devices in 3 patients (Symbion in 2, Nippon Zeon in 1), and a Novacor left ventricular assist system in 1 patient. The mechanical circulatory support system was connected in all patients but 4 (the patients with ventricular assist devices) under cardiopulmonary bypass. Selection of the device was made in the operating theater using clinical, hemodynamic, and echocardiographic (in the last 3 cases) evaluation of the right ventricular function.

Improvement of hemodynamic condition was spectacular in all but 1 patient, because of a progressive loss in vascular tone on day 3. Organ function did not recover in 2 patients. In addition, the condition of the patient stable on the Novacor left ventricular assist system deteriorated suddenly after 9 days, due to a recurrence of acute myocardial infarction in the right ventricle. Five patients could undergo transplantation after stabilization on day 5 (range, 3 to 12 days). Two died after heart transplantation owing to irreversible multiple organ failure. One died of septic shock while on dialysis on day 9 after transplantation.

Pharmacological Bridge Patients

The 44 patients who initially improved had a variable evolution. The condition of 13 patients deteriorated after 7 days (0.5 to 14 days), and in 31 patients the hemodynamic situation either stabilized or improved dramatically, mak-

ing possible either weaning off drugs or transplantation on an elective basis. As a whole, the results are as follows.

In 12 patients, a contraindication led to the postponement of transplantation. This decision was made in 15 days (range, 2 to 43 days), because of cancer, epileptic seizures, sepsis, chronic alcoholism, poor compliance, and a complex social environment. Four died within a month, because of sepsis in 1, brain tumor in 1, and multiple organ failure in 2. The others could be discharged and kept alive in New York Heart Association functional class III under oral medication. Eight were still alive at 1-year follow-up. In 1 patient, the improvement in the familial and social environment led to a reconsideration of the previous decision. The patient underwent transplantation and died of pulmonary infection after 6 days.

In 6 patients who initially improved hemodynamically, the lack of rapid recovery of organ failure led to contraindication of both implantation of a mechanical circulatory support system and in 3 patients transplantation itself. In 3 patients, the transplantation was performed, as a life-saving procedure, within 4 days. Only 1 patient survived. The 2 others died because of multiple organ failure in 1 and graft failure in 1.

In 26 patients, indication for cardiac transplantation was reconfirmed within 14 days (range, 0 to 95 days). The condition of 4 patients deteriorated suddenly, because of ventricular fibrillation in 1 and electromechanical dissociation in 3. Only 1 could be implanted with a Jarvik. His condition deteriorated rapidly due to loss of vascular tone. In 14, the transplantation was performed after 11 days (range, 0.5 to 27 days). Nine patients could be discharged. In 8, the lack of organ available and the continuous improvement of clinical condition led to their discharge. In 3 patients the transplantation was performed successfully after 75, 102, and 181 days. Two patients died suddenly while waiting for transplantation at home, after 42 and 161 days. In 2, the indication for transplantation disappeared. One is still on the list after 5 months.

In the present group of 26 patients reconfirmed for transplantation, an index of risk of death of patients treated in the intensive care unit (SAPS index [3]), based on 14 easily measured biological and clinical variables, was computed on the day of institution of intravenous enoximone therapy and the day of transplantation (in 14).

Table 1. Hemodynamic Changes After Intravenous Enoximone Bolus Injection

Time (h)	Urine Output (mL/h)	Heart Rate (beats/min)	MAP (mm Hg)	PAP (mm Hg)	PCWP (mm Hg)	Cardiac Index ($L \cdot min^{-1} \cdot m^{-2}$)	SVR ($dynes \cdot s \cdot cm^{-5}$)
0.00	38.82 $\pm$ 4.68	104.21 $\pm$ 2.68	73 $\pm$ 3	50.91 $\pm$ 2.52	28.65 $\pm$ 1.43	1.71 $\pm$ 0.07	1,594 $\pm$ 95.15
0.30	87.86 $\pm$ 4.92	102.04 $\pm$ 2.40	72 $\pm$ 3	47.07 $\pm$ 2.24	21.50 $\pm$ 1.38	2.66 $\pm$ 0.13	1,176 $\pm$ 80.03
2.00	87.92 $\pm$ 5.32	101.54 $\pm$ 3.65	71 $\pm$ 3	42.87 $\pm$ 2.11	20.25 $\pm$ 1.64	2.53 $\pm$ 0.11	1,226 $\pm$ 89.95
4.00	95.00 $\pm$ 3.45	97.78 $\pm$ 5.05	73 $\pm$ 3	47.22 $\pm$ 2.50	24.83 $\pm$ 1.81	2.46 $\pm$ 0.11	1,249 $\pm$ 85.48
8.00	90.91 $\pm$ 5.18	102.68 $\pm$ 3.30	74 $\pm$ 2	51.50 $\pm$ 2.31	25.77 $\pm$ 1.72	2.10 $\pm$ 0.15	1,464 $\pm$ 121.33

MAP = mean radial artery pressure; PAP = pulmonary artery pressure; PCWP = pulmonary capillary wedge pressure; SVR = systemic vascular resistance.

Fig 2. Evolution of the SAPS index in the group of patients reconfirmed as good candidates for transplantation during the waiting period. Patients who will die after transplantation owing to multiple organ failure (MOF) (▲) have been transplanted after an incomplete improvement of the SAPS index. Patients who will be free of any organ dysfunction after transplantation (★) were more improved while waiting for the graft. The shaded area represents the value of the SAPS index, which has a low prognostic value.

The mean values of patients who will be successful or who will die of multiple organ failure are represented in Figure 2.

As a whole, at 1 month, 29 patients were alive (55%); 13 underwent transplantation, 3 after a mechanical bridge and 10 after a pharmacological bridge. Eight are still waiting for the transplant and are stable at home. Eight patients with some type of contraindication are in stable condition on oral medical therapy. At 1 year, 19 patients were alive (37%), with 13 receiving transplants after a mechanical (in 2) or a pharmacological (in 11) bridge. Two are in stable condition and New York Heart Association class I; they were withdrawn from the transplantation list because of spectacular ventricular improvement. Four patients with a contraindication are still living on medical therapy.

Comment

A few comments are necessary for a better understanding of the present strategy. First, the concern about the cost-effectiveness of the management of the patients about to die is a situation imposed by the present expectations of society and the various institutions involved in payment for health care. The second comment is about the origin of the patients admitted in cardiogenic shock who may be candidates for a mechanical bridge to transplantation. Most are not, in our experience, patients whose condition deteriorates while they are waiting for cardiac transplantation. This is due to the policy of our institution based on the most urgent-first served principle. This might also be due to the care given in the evaluation of prognostic indices in the transplant candidates. The selection is based on analysis of metaiodobenzylguanidine cardiothoracic ratio [4]. The relatively high

number of urgent patients referred for immediate transplantation or mechanical bridge may also be the result of the position of Henri Mondor's hospital, to which a third of the cardiac emergencies of the whole Parisian area are referred.

The previous publications [1, 2] of our group have emphasized the benefits of the pharmacological bridge strategy in terms of cost savings, cost-effectiveness, and saving of cardiac donor grafts. The present report focuses on the limits of our strategy.

The limits of the strategy are obvious. The outcome of the 3 patients of 8 who are unresponsive to enoximone and who received a mechanical circulatory support system is unsuccessful, owing to loss of vascular tone and irreversible multiple organ failure. The loss in vascular tone has been related to a consequence of prolonged pharmacological support [5]. The irreversible evolution of organ failure has been shown to be more frequent in patients implanted late [6]. The limits of the strategy are also obvious in the patients initially dramatically improved within the first 8 hours of intravenous enoximone. Two different modes of failure may be considered: sudden death and poor physical rehabilitation during the waiting period.

The rate of sudden death appears unacceptable in the group of patients reconfirmed as good candidates for cardiac transplantation. Four of the 26 patients (15%) died as they were waiting in the intensive care unit for a suitable graft. In addition, 2 died suddenly in the group of 8 patients successfully discharged from the hospital. Adequate management of such an acute complication is most difficult, and resuscitation procedures are unlikely to be successful. The risk of failure of the pharmacological bridge appears to be unacceptably high in the group of ischemic patients [7].

The second problem is related to the incompleteness of physical rehabilitation of the patients improved hemodynamically by intravenous enoximone. In the group of patients who could not be discharged, the SAPS index clearly shows that the situation at the day of transplantation is not optimal. The unacceptably high number of patients dying within a month after transplantation because of multiple organ failure is probably a consequence of the incomplete rehabilitation. This observation has to be considered when the time required to obtain a suitable donor is increased. It should lead to implantation of a mechanical system, permitting prolonged and safe waiting time.

The present experience, obtained in the management of a substantial number of patients, helps the evaluation of the real role of pharmacological bridge in the management of the patients in cardiogenic shock who are candidates for cardiac transplantation. The data show clearly that there are indications of mechanical devices, because of the limits of the pharmacological bridge, both at the time of admission and after a few days.

In conclusion, the present limitations of the pharmacological bridge pointed out in the present study should not cause one to underestimate the benefits developed previously. They emphasize the problems encountered in daily

practice, when attempts are made to offer the patient the most cost-effective management.

FDA Regulatory Issues Session

How Much Do We Need to Know Before Approving a Ventricular Assist Device?

Moderator: J. Donald Hill, MD

Panelists: Bette Lemperle, BSN, MPH, Mark Levinson, MD, Victor L. Poirer, BSME, and Bartley P. Griffith, MD

MODERATOR HILL: Each of us here has a different role to play in how to help patients in the very best way. The goal here today is to have a dialogue among these various interests to discuss the motives, goals, responsibility, and accountability involved in developing a ventricular assist device to the point where it can be successfully used in our patients. It is a complex issue that has evolved through the years. But it is one we must work through, we must understand, and we must solve so we can make these devices safe, effective, cost-efficient, and helpful for our patients.

There are various interests in society that address this issue, and each has its own different viewpoint. First are those in medicine, who are the advocates of the patients and are doing everything possible to help them. Then there is the Food and Drug Administration (FDA), which regulates devices and is held accountable by society to make sure they are safe and effective because patients themselves are not in a position to judge that. Next, there is industry, which has a responsibility to both society and its shareholders. Then, there is the National Institutes of Health, which, although not always in the loop, is accountable for rigorous research on these devices to make them worthwhile for society. And finally, there is the patient. We must never forget that it is the patient for whom we all are really working. We have to be accountable to patients, as well as ourselves. Together, through dialogue and compromise, we can determine how best to solve this complex issue.

With that short introduction, let us begin with four presentations. Each represents one of these different segments of society and will cover its role and responsibility in the process. The model we develop now for some of these life support systems will be one we use in the future, so it is crucial we do it well and everyone be properly represented so that it is the patients who ultimately benefit.

To begin is Bette Lemperle, who represents the FDA.

BETTE LEMPERLE: Thank you for inviting me to present the FDA's view on the topic "How Much Do We Need to Know Before Approving Ventricular Assist Devices?" This subject has been on the minds of many people involved in this type of work for several years.

Indeed, many suggestions are offered in this regard, particularly at meetings such as this one. Some of you have suggested that there should be a provision for the use of prototype devices in up to 200 patients before the FDA ever gets involved in an investigation or approval. Others have suggested a more modest number of 7 or 10. Still others suggest that although early FDA involvement with new devices is warranted, it is sufficient for us to know that a device meets certain test parameters in the laboratory and in animals, and that as a pump it pumps without failing in the clinical setting.

Although there is general agreement with the basic principles underlying the FDA's oversight of clinical research, not everyone agrees on how these principles should be translated into the specifics of how much in vitro testing is sufficient, how many animals should be tested with the device, what are the appropriate patient selection criteria, how success should be defined in the clinical trial, what end points should be measured, and what is an appropriate follow-up protocol.

In the early days many investigators, enthusiastic about these new systems, viewed them first as potentially life-saving therapy for their dying patients, with data collection and protocol compliance being distinctly secondary concerns. Potential investigators did not appreciate the FDA's role in limiting the availability of these, yet unproven, investigational devices. There was resistance to the FDA insisting on a degree of uniformity in study protocols and data collection to decrease the potential for bias. The FDA, on the other hand, contended that by not conforming to these requirements, investigators were adding to the delay in getting potentially useful devices to the market and available for wider use.

The FDA has attempted with some success to address these issues through a continuing dialogue with the clinical investigator community and the professional societies. As a result of this cooperative dialogue, the scientific documentation of the clinical safety and effectiveness of these devices has evolved to a point where market release of one or more short-term use ventricular assist devices (VADs) appears to be near.

In a group such as we have assembled here, there are usually many people who are unfamiliar with the law and regulations governing FDA device review and approval. Therefore, before proceeding with the discussion of the type of data that we require to demonstrate safety, effec-

tiveness, and clinical utility of the VAD, I will briefly summarize the aspects of the Medical Device Amendments of 1976 and the Safe Medical Devices Act of 1990 that are pertinent to this discussion.

The Medical Device Amendments of 1976 established a three-tiered system for regulating devices. The Safe Medical Devices Act of 1990 further defines the system. In the three-tiered system each tier, or class, is based on the extent of control necessary to reasonably assure the safety and effectiveness of the devices. Class I devices, such as the surgical scissors and manual stethoscope, are only subject to general controls, such as good manufacturing practices, quality assurance in manufacturing, and labeling. Class II devices such as x-ray and ultrasound equipment can be marketed subject to general controls and special controls such as compliance with voluntary or mandatory performance standards, postmarket surveillance, and additional preclinical and clinical performance data requirements that the FDA may consider necessary. Class III devices such as heart valves and implantable defibrillators are life-sustaining or life-supporting devices for which general controls and special controls are insufficient to assure safety and effectiveness and which, therefore, must undergo the premarket approval process. Total artificial hearts and ventricular assist devices fall within the class III regulatory category.

Regulations developed to enforce these laws provide for three types of medical device applications to (1) legally market the device, (2) conduct a clinical investigation of a device, and (3) seek approval to market a device. The applications include the Investigational Device Exemptions (IDEs), the Premarket Approval Application (PMA), and 510(k) or premarket notification. 510(k)s are not applicable to VADs at this time. Investigational Device Exemptions are intended to study the safety and effectiveness of medical devices in humans after sufficient preclinical data demonstrate the relative safety of the devices. For certain class III devices, the manufacturer submits the preclinical and IDE data in a PMA application. The PMA application is reviewed by FDA scientists, and it may be submitted to an advisory panel at the FDA's discretion. Advisory panels, which are composed of physicians, scientists, consumers, and industry representatives, regularly assist the agency by making recommendations on the safety, effectiveness, and clinical utility of new devices. Their participation in the approval process adds a critical perspective from the academic community and the everyday world of medical practice as a complement to the FDA's scientific and technical review. The PMA application process allows the agency to determine if a class III medical device has been shown to be reasonably safe and effective for its intended use, and therefore suitable for marketing.

Mandates of the Act and subsequent regulations require that clinical trials on medical devices meet certain standards for the protection and welfare of human subjects and for the orderly collection of clinical data. The three basic requirements are as follows: (1) A risk-benefit analysis, based on objective criteria, must demonstrate that the benefit to the individual patient in terms of likely

therapeutic value, and to society in terms of knowledge to be gained, outweighs the foreseeable risk to the patient. (2) Informed consent is to be obtained. (3) An Institution Review Board and the FDA provide peer review of the proposed clinical trial. These are the requirements of good science and good clinical research, not unlike those imposed by the NIH for funding clinical research, and are derived from landmarks such as the Nuremberg Code, the Declaration of Helsinki, and the Ethical Guidelines Statement of the American Medical Association.

In carrying out these requirements, the FDA looks closely at the safety, effectiveness, and clinical utility of the VAD systems that are proposed for premarket approval. During the early years of these clinical trials, the FDA did not play a very active role in attempting to define clinical protocols for data analysis strategies. The focus of our review was on the rationale for the device design, assessment of the compatibility for blood- and tissue-contacting materials, evaluation of design material factors such as resistance to thrombus formation, evaluation of potential causes for damage to blood components, characterization of the device, assessment of device durability and reliability, and its performance in vivo. This was a learning period for sponsors, for investigators, and for the FDA. Many new and unique questions and concerns were addressed and procedures and policies were progressively developed. The sponsors were relied upon to do what was necessary to optimize the scientific yield from the clinical trials.

The same type of preclinical data are required today, and the FDA must determine that these data are acceptable before approving a PMA. The questions that come up most frequently in regard to preclinical data are the FDA's requirements for in vitro and animal testing. I will briefly summarize these requirements.

All preclinical testing required for circulatory assist devices must be performed on the final clinical design to be used in the clinical trial. When the information is submitted, the FDA expects it to be comprehensive and collected methodically according to established norms of good clinical science. The FDA also expects the results to be appropriate for the intended use of the device and to demonstrate reasonable assurance that it will perform safely in the proposed clinical population. In vitro studies encompass materials testing, flow visualization, design validation, and device characterization. The device characterization study must include the data collected under an orderly array of conditions that represent the total range of conditions that could occur during clinical use of the device. This would include (1) use of the system in all modes of synchronous and asynchronous operation; (2) the value ranges required to attain the cardiac outputs anticipated in the clinical setting such as air pressure, beats per minute, right and left atrial pressures, and percent systole; (3) peak pressure gradients across the valves and peak pressure at the exit ports for each cycle for each parameter range; (4) parameters of operation under worst-case physiological conditions, that is, the highest flow and lowest flow under which the pump can operate and threshold conditions that will cause the

pump to fail; and (5) Starling's curves for operation of the device.

The durability and reliability testing includes (1) a description of test results for a minimum of eight systems, of which four are removed and examined after 6 months and four are allowed to run to failure. The system should be run under worst case and normal conditions based on the results of the characterization study. (2) The model used to predict reliability must be presented also. Currently 80% reliability with a 95% confidence or better is acceptable. (3) The results of the study must include a detailed examination of all components for wear and cracks, with special emphasis on the diaphragm and the valves. These components should be examined by scanning electron microscope, thermal imaging, and other high-magnification examinations. In addition, information on fatigue, the predicted life of the system, the predicted life of critical components, and the maintenance schedule based on all of these factors is required. (4) All failures must be described including when they occurred, why they occurred, whether they could be resimulated, whether the component could be changed, the potential effect of a failure on the clinical situation, whether the reliability test was continued after failure, and the actions taken to prevent their recurrence.

To satisfy our in vivo requirements, a minimum of 8 animals must have the device implanted for at least 4 months. The primary objective of the in vivo evaluations is twofold: first, to observe how the device performs in the physiologic environment that is similar to clinical use, and second, to observe the physiologic changes that occur in response to the implant. A secondary objective of the in vivo study is to confirm the findings in the in vitro tests. In this regard, the FDA expects to see the devices used in the animal studies explanted and evaluated for wear. The FDA also requires hematology and blood chemistry study results for each animal and for all animals including the mean preimplantation and implantation parameters at regular intervals for the period of implantation; complications that occurred during each animal implantation and a summary of the rate of occurrence of each type of complication for the group; and reports of explanted devices for each animal with diagrams and photographs as necessary to illustrate the appearance, results of microscopic examination of component wear and deterioration, a description of the location and size of thrombus formation, and results of histopathological studies. Autopsy reports should also be provided for each animal, with pictures of the device in situ, autopsy examination with conventional histological studies of major organs, and histological evaluation of all areas of grossly evident pathology. We would also want information on changes made to the device or to the proposed clinical trial based on the results of the animal study.

Occasionally, study sponsors will inform the FDA that the animal model is not appropriate for evaluating clinical readiness of their device. The FDA will consider documentation supporting this position. However, there have been studies where adverse effects that occurred during the animal trials were attributed to the animal model, but

when the clinical trial was subsequently initiated, these same events that had been attributed to the animal model were replicated early in the experience. So animal trial findings continue to be an important feature in judging the clinical readiness of a device.

About 5 years ago it became clear to the FDA that its prior policy of relying on sponsors and investigators to do what was necessary to optimize the scientific yield from the clinical trials was not sufficient to move the studies toward premarket approval. Study sponsors were not defining, directing, or monitoring their studies with the kind of control and goal orientation necessary to develop scientific data for eventual determination of safety, effectiveness, and clinical utility. After consulting with the scientists and clinicians in the Center for Devices and Radiological Health, members of the Circulatory System Devices Panel, and consultants from other medical device panels, it appeared that the data being submitted to the FDA were preliminary and could best be used as baseline information for formulating questions to be answered about clinical effectiveness and utility in appropriately designed second-phase clinical trials.

The FDA maintains that a pilot study is valuable and that a second-phase trial with experienced investigators implanting devices in appropriate patients can be conducted expeditiously. The anticipated results are data of a quality suitable for a final analysis to determine VAD safety and effectiveness as a bridge to transplantation or for weaning from bypass. Some sponsors have completed this process, and an earlier satisfactory overall conclusion to the evaluation of their experience is anticipated despite their initial frustration.

From the inception of the IDE, new study sponsors are encouraged to design studies using sound scientific principles. Some of the items that must be addressed are: (1) What are the questions that need to be answered about a device and the effect on an intended population? Specifically, what do we expect the device to do? What patient population do we target? How do we define that patient population? (2) We need to know the general and specific study objectives based on these questions. For instance, in the postcardiotomy patient we would want the sponsor to demonstrate that the device can provide effective hemodynamic support, that it allows for myocardial recovery, and that it allows for survival in 20% to 30% of the patients who meet the selection criteria. (3) We need to know how success or failure of study objectives will be demonstrated. For instance, how is the device expected to perform hemodynamically in the patient? How will vital organ function be measured? How is the control group defined? What types of adverse events are anticipated? What rate of adverse events is acceptable? What number of study patients and control patients is necessary to demonstrate safety and effectiveness? What number of centers will be needed to obtain the data in a reasonable period of time? What controls will be instituted to address the inclusion of multiple centers? How long should patients be followed up? What data should be collected during follow-up? (4) What specific data parameters will be collected to demonstrate success or failure? How will

the data be normalized to address the differences between the centers? What type of format will be used for recording the information? (5) Finally, what type of analysis will be performed on the data, and what statistical methods will be used in the analysis?

The FDA expects sponsors to establish continuity between the questions to be answered, data to be collected, the size of the study, and all the steps leading to the proposed analyses. Otherwise, conclusions drawn from the study may be unacceptable.

Control or reference group data are essential and should be collected from the outset of clinical implantation. If patients are their own controls, as is common with the VAD weaning indication, time frames for attempting weaning with drug therapy and intraaortic balloons before VAD therapy must be established and adhered to. The assumption is that before entrance into the study, no apparent irreversible end-organ function has occurred and the device may be evaluated by its ability to maintain appropriate pressures, flows, and patient hemodynamics; to protect end-organ function; to promote myocardial recovery; and thereby to promote survival. With the bridge indication, the FDA expects clinical centers to track transplant patient populations who meet the same study entrance criteria as bridged patients but do not receive the bridge device.

Uniform study criteria, entrance criteria, procedures, and interpretation of adverse events are essential for both intracenter and intercenter pooling of data. Justification must always be given for pooling among study centers. With a large number of study centers and investigators in VAD studies, uniformity becomes a critical issue in judging pooling of data for analysis. For example, data have been reviewed by the FDA where as many as half of enrolled patients did not meet entrance criteria. This can be attributed in part to the tendency of some investigators to reason that if the device has worked well for long periods to bridge patients who meet standard heart transplant criteria, perhaps it will work well in patients who do not meet transplant criteria, reversing severe end-organ dysfunction and thus allowing sufficient recovery to permit transplantation weeks or even months later. This may be true, and may identify a subsequent group of patients to be studied. The problem is that by adding a new group of patients, a separate study has been initiated before the original questions have been answered, and it is likely that both study and premarket approval will be delayed. Indeed, just how much clinical data will be required to approve a VAD is greatly related to the number of VAD study patients and control patients entered into the study who meet study entrance criteria and the difference in outcome between these groups. If most of the patients implanted with the device do not meet entrance criteria and control data are not collected, the final results cannot be evaluated.

Both bridge to transplantation and recovery protocols currently require patients who enter these studies to have adequate end-organ function or dysfunction considered reversible. This is needed to assess the effect of the device on end function. Every attempt should be made to accu-

rately document end-organ function before device implantation. Consequently, when a patient is on a device beyond the time it normally takes to recover from the effect of cardiopulmonary bypass and other hematological insults, hematology and blood chemistry parameters that reflect end-organ function status are expected to be maintained at reasonable levels or improved as compared with preimplantation levels. Therefore, patients with irreversible end-organ function are not eligible for these studies, and if they receive implants as emergency use protocol deviations, their data should be analyzed separately from the core patient group.

Another uniformity issue concerning study entrance criteria is defining heart transplant candidates. When bridging was initiated in 1985, each heart transplant center's criteria for transplantation were based on the Stanford criteria, and criteria varied little from center to center. At that time it was sufficient to state that patients who met the center's heart transplant criteria could be entered into a bridge to transplantation study. Today, however, transplant criteria vary from center to center, and it is no longer sufficient, in a multicenter study, to state that a patient may enter the study after meeting the heart transplant criteria at his or her center. Study entrance criteria must incorporate those heart transplant criteria that define a specific study population. This does not mean that all centers must use the same heart transplant criteria as those specified for the study. Rather, only those patients who enter the study must meet the same transplant criteria.

Evaluation of adverse effects also has limited utility when each event is not specifically defined. Although accepted uniform definitions are lacking within the medical community at this early stage of the technology, each investigator must have a basis for making a declaration about an event that ensures conformity or at least comparability with such decisions at other study centers. Definitions developed for these early studies may well be the basis for generally accepted definitions across all VAD studies in the future.

The issue of uniformity extends to implant procedures, patient management, autopsy protocols, and explanted device analyses. When uniform procedures are not followed, the reason must be documented. This information is extremely important to the overall analysis.

In addition to appropriate study design and procedures to assure collection of reliable data, the FDA has also focused attention on actual data collection used to evaluate study end points and to answer the important questions about device function in the indicated patient population. For valid conclusions to be drawn, these data must be collected for all patients at specific times in the same manner. Otherwise, use of the most appropriate statistical methodology to support a conclusion is worthless. If the study is supposed to demonstrate that the device can increase cardiac output to levels consistent with survival in hemodynamically compromised patients, data must be collected to demonstrate patients' hemodynamic parameters before implantation and at regular intervals subsequent to implantation. Similarly, to dem-

onstrate that the device does not cause hemolysis, kidney failure, or untoward neurological effects, data must be collected for baseline information before device implantation, during device use, and after removal. When data are aggregated to demonstrate device effects on patients, only data for those patients for whom all of the data were collected can be used in the analysis. Sometimes data from autopsy reports or device analysis studies are used to demonstrate that a particular anticipated effect or patient injury was not observed in the study. Such data must be qualified with information on the number of autopsies and device analyses that were actually performed. For example, if 10 patients die, but only two autopsies are performed, less weight is given to the findings.

These are just a few of the examples of VAD protocol and data issues with which the FDA has been grappling in the regulatory role. There has been progress amidst these many complexities, and it is anticipated that the Circulatory System Devices Panel will soon be evaluating data in preparation for making recommendations on several systems currently under study.

MODERATOR HILL: We will have the discussion immediately after each presentation, so that if there are questions on people's minds directly pertaining to the presentation, they can bring them up while they are fresh in everybody's mind. Are there any questions that anybody would like to bring up or discussion points on the presentation?

DR WILLIAM L. HOLMAN (Birmingham, AL): The implication of your talk was that any compassionate use outside of protocol will actually delay the approval of the device. Did I understand that correctly?

MS LEMPERLE: Well, the data cannot be used in the analysis. So that would be collecting data that are not usable. They can be used to a certain extent, but not in the core analysis to substantiate effectiveness.

DR HOLMAN: Okay. Just what is the FDA's general view of compassionate use of these devices? I will give you an example. Suppose you have a patient who has had a pulmonary embolus, and pulmonary embolism in your institution is considered a contraindication for transplantation unless you can document resolution of the embolus, which usually takes several weeks. Therefore the patient falls outside of protocol. He or she is not at the time that you need the device a candidate for transplantation. It is that kind of situation that we deal with from the standpoint of clinicians. The patient is going to die, but is outside protocol. Should you use the device even though the data cannot be used? What is the FDA's feeling about that? If we use too many, are we going to have a problem with the FDA?

MS LEMPERLE: We leave the decision as to whether you can use the device or not up to the sponsor of the study. It is their study. They have to get the data. But

when we evaluate the data and we see that none of the data from some investigator can be used in the study, we might question why they would want to keep that investigator in the study.

SPEAKER: Does the FDA differentiate between data collected in Europe or the United States? If there is some modality used in Europe earlier than in the United States, do the data add to the collection in the United States?

MS LEMPERLE: It would depend on the situation. There are occasions when European data are used for a PMA. But generally the data for an IDE are collected in the United States. The problem is that we have to demonstrate that the patient populations are identical, that the protocol was followed, and that informed consent was collected. And that is often difficult to collect in another country.

DR ERIC A. ROSE (New York, NY): You state, I think quite legitimately, that a risk-benefit analysis is an important part of your assessment of the appropriateness of a clinical protocol. It seems that the FDA is beginning at least to consider risk-benefit analysis in terms of the stringency of its regulation of introduction of new technologies as well for certain disease states. We see that now drugs for human immunodeficiency virus and drugs for malignancies seem to be fast tracking through your system. One does not get the sense that type of fast track yet exists in the field of end-stage heart disease. Could you comment on that? Do you have the perception that a risk-benefit analysis should be appropriate for device approval in this area of end-stage heart disease?

MS LEMPERLE: I would think that your interpretation is correct; it has not reached down to this area and we have not discussed it yet.

MODERATOR HILL: The next speaker is Mark Levinson, who is a surgeon and a member of the FDA's Circulatory System Devices Panel.

DR LEVINSON: My particular role in this is as a member of the Circulatory System Devices Panel. This panel consists of physicians who act in an advisory capacity to the agency at the time of premarket approval. For those of you who are not familiar with my background, I am currently a cardiovascular surgeon practicing in Seattle. My training in devices took place primarily at the University of Arizona. After leaving Arizona, I was invited to be a member of this panel in about March of 1988. Subsequently, I have had the chance to review applications for various types of medical devices in my specialty such as cardiac valves, vascular grafts, pacemakers, laser angioplasty, and atherectomy devices. We are now entering an era when we are going into the complexities of circulatory assist devices.

I thought I would just review some of my own experiences. The Circulatory System Devices Panel is a limb of the agency that attempts to inject some peer review or

physician review into this approval process. The FDA, itself, is a regulatory agency created by consumer law. I have detected a lot of feelings in this audience in the last few days about how difficult it is to get devices through to final market. But the fact is that this frustration is a direct result of our own legislation in this country, and has been driven by the legal profession and consumer law. We now have to administrate this law as effectively as we can. It is intended to reduce victimization of the patient by devices that are incorrectly designed, inappropriately marketed, or in some cases, are frankly irresponsibly created. The Circulatory System Devices Panel attempts to inject its practice patterns and its feelings about device safety and effectiveness into this process. Often I call on myself to ask this important question: "Would I let someone implant this device in my own father?" And if I believe it is safe and effective, then I am generally able to answer that question affirmatively and vote for approval.

The panel has been asked to make its decision on what has been termed as "valid scientific evidence" of safety and effectiveness. A standard has been set up in the agency that this should take place through a prospective clinical trial. There are a lot of other strategies, but a clinical trial is the standard by which we base our decision. We are not able to use peer review literature, case reports, anecdotal experiences, or even the market history of the device in other countries as reported through peer literature or personal experience to approve these devices. There must be a prospective trial. So in a sense that trial becomes the most important document in making these decisions.

I think from the sponsors' standpoint, you must understand that the panelists see this document at the end of your second-phase IDE trial. Essentially, we are injecting ourselves late in the development of this trial. The only thing we are expected to evaluate is the document itself, so the organization of that document and the quality of the materials in that document will determine how we interpret it.

Another thing that I often emphasize to sponsors is that the burden of proof rests with you. It is not up to me to find the material that has been held back, or the missing data. We will just be left with inadequate support for this decision. The burden of proof rests with the sponsor, and that is often lost in the morass of these trials.

Let me just discuss a little bit about the guidance document that is often mentioned. The FDA has attempted to provide a rough framework for structuring these protocols. I think Bette Lemperle has given an outstanding summary of what the current viewpoint is on circulatory assist devices. But I would like to stress that the guidance document that is currently available is preliminary. It is not a final version, and even so, with the final version, this is intended to be a framework. The panel will often insist on even more than is in that guidance document. We have seen sponsors who have said to us that we are asking for data that was not requested in the original guidance. And yes, that is absolutely true. The guidance is a rough skeleton upon which to build a good clinical trial. I think that you should

always consider building upon that. If you fail to capture pertinent data early in the trial, the opportunity to analyze them and to reach conclusions from those data is lost. And after studying 100 or so patients, if some vital information is not included in the initial trial, all of that effort will be wasted.

Let me talk a little bit about protocol structure. I mentioned that we are very, very dependent on the final PMA submission during the approval process. I will say that in device technology, it is important to very intensively survey a small number of patients for a short time. We will never see a large series with these devices. So, the intensity with which you survey the patient is going to increase the information quality that we get when you submit the device for panel review. Thus, the protocol has to be set up well and it is very, very helpful to involve your principal investigators in the design of the study.

I was struck by Peer Portner's slide this morning when he described his steering committee in setting up the NIH clinical trial for the long-term implantation of the Novacor device. I think this approach is essential and yet often neglected. Usually I see companies who have charged their vice president of regulatory affairs with coming up with a protocol that will satisfy the FDA. This may not satisfy physician panel needs four years later. Involve the physicians early and continuously, and get their feedback. If they need certain parameters in that trial, find a way to get them. Physician panelists in the same related specialties four years later are going to be asking for that information, and if it is missing, it really will cut down on the quality of our analysis of that study.

Another important point is to keep in frequent contact with the agency. Bette Lemperle is the chief person in charge of IDEs for ventricular assist devices and total hearts. I have seen several applications that suffered because the sponsors were unwilling to keep in frequent touch with the agency and get their questions answered early in the trial or to cooperate with the agency so that major holes in the project can be patched early before eventually reaching panel review. Once you reach panel review, if there is missing information, it will hurt.

Let's go to the subject of selection criteria, which has been mentioned over and over in this two-day meeting. As a practicing physician who has used these devices, I have a slightly different view than some of the regulators in the agency. At the time I review these applications, I think I have a feeling for the physician's concerns at the time the decision is made to implant these devices. I do not entirely agree that selection criteria have to be rigidly enforced at the bedside. We all know the patient has only hours to live. We have to make a decision to implant the device and what to do. Although our inclusion and exclusion criteria are intended to stratify the study, there are going to be protocol deviations. There are going to be compassionate uses. My emphasis to the sponsors is to make sure that you are willing at all times to collect data on all these patients and subgroup them for analysis.

Just the same, you must identify a primary target group. That primary target group will eventually have to reach a number of subjects that is large enough for us to

analyze as a primary indication for the device. So, if there are significant numbers of protocol deviations, we will eventually start to wonder which is the primary target group. If there is an occasional compassionate use, those people fall out as outliers, and they are very easy to deal with at panel review if the target group is well studied.

Next, it is important to delineate and decide what the expected morbid complications are and define them. Definitions for these complications must be applied universally to all the patients across all the centers. If one person is calling something an apple and another person is calling it an orange, the statistics are not meaningful. The steering committee is of tremendous value in establishing not only the primary target group but also how morbid complications are defined. At the end of the analysis, I am going to look at those definitions and I expect that your incidence of complications reflects that definition. But if the definitions keep changing from center to center, I will question what the incidence of those complications really means.

In that respect, I have seen several studies in which the data collection forms and the methodology varied from center to center. That is a very bad practice, overall. Sponsors should insist that the principal investigators maintain common reporting methods as much as possible. If you are going to stratify or quantify events, if you are going to use a check form or an on-line computer database, everybody should follow the same reporting practices. Then we know what the data mean.

I think it is important that a sponsor takes a very close look at its potential study centers. This is a tremendous commitment, and the centers need to be able to provide the resources to capture the data up front. If they are interested in the device but they do not have the in-house personnel, if they do not have the commitment, or they have never done anything like this before, it is going to be hard to get this information back to the company on each and every one of these implants. And it will just make it harder to get to panel review. It is always sad to see a good device come to the panel with one center carrying two-thirds of the information, and the other centers have used it only a few times and there are no data. That really is not a multicenter trial.

I am rather biased in having direct physician input in follow-up and complication reporting. I think that one of the things I would like to see, which is not currently done in VAD protocols, is for the principal investigator to create a summary of the case for each patient. I have found a tremendous value in reading PMA applications when I actually get a summary of each case. There are often a lot of tabular data in PMAs. There are a lot of graphics generated from the sponsor's computer, but I want to know what happened at the bedside. And the best person is the principal investigator. Often they assign their study coordinator to fill out the check list, but I think the FDA should ask that the principal investigator dictate a summary of every case. What happened in the operating room? What happened in the intensive care unit? What led to the death of the patient? This is extremely hard to reconstruct from the patient's chart by a study coordinator

sent to the center two months later, and that decreases the value of that information.

I cannot over-emphasize the importance of autopsies. I have personally seen applications where the autopsy report has been valuable in establishing a patient-related complication and removing concern about device-related complications. We expect to see postmortem reports in the application so that we can see the wording ourselves. They are extremely valuable. Operative reports have equal value and should be copied and forwarded for every case. The same is important for critical radiographs. If you have a large series of left ventriculograms or multigated acquisition scans and you are looking for a significant difference, have them reviewed by an outside, independent, blinded interpreter. A simple report that the principal investigator says "this is an improved ejection fraction" may not be valid.

Explant analysis! I think this is an extremely important point. It is a unique opportunity to prove that your device is working, that it did not break, that it did not clot, and that it did not get infected. I want to encourage each sponsor to develop a standardized methodology for explant analysis that is common to each trial center. Insist that the device be sent back. Tell them how to do it. Provide them the equipment. In addition, I think the explant analysis should have a semiquantitative scoring system so that you can look at things such as sites of thrombi and extent of infections. Use a semiquantitative way of presenting these data to the panel.

Do not be shy in getting metallurgy, scanning electron microscopy, and other forms of failure analysis. Those types of things are very solid information when we want to know why the device broke. And if that problem was identified and fixed, it will be interpreted in your favor at panel review. Aggressively test any device that you or the investigator think has failed. For the same reasons, we want to know what happened, or what might have happened, to the patient if you pushed the device all the way to failure, and what those failure modes are. If a device is working outside of its normal range and you receive it back, test it to failure and make a full report so we know what happened. There is a chance that somebody on the panel will spot this problem and ask you how that device performed on the bench.

I would like to mention another issue about study centers. Sponsors should be willing to shut down centers that are misusing the device or habitually violate the protocol. We have seen such violation. It is very damaging to the final analysis of the study, and it does not do patients any good. I also believe that if the center is failing to capture the data, that is just going to hurt you during the subsequent PMA approval process.

Regarding the panel meeting itself, here are a few clues about what I like to see. Bring the device. You would be surprised how few people bring the device. There are some people who have never seen it and who are sitting on the panel about to decide whether you should market it. I think that there is something to the "seeing is believing" concept. Bring the investigators who have implemented the largest number of devices. These are

people who know about what is going on. They can answer questions by panel members regarding what the complications reported during the trial meant. If they have had problems, we want to talk to them and find out what their responses to those problems were. Do not forget to bring special consultants. You have in-house engineers, physical chemists, and hematologists who help you set up this program. You have quality control people who will be able to answer specific questions about the manufacturing of the device. Bring your grassroots people from the company. Bring your engineers and your study coordinators, because there just might be a key question that they can answer better than anybody else.

Prepare for questions by bringing your raw data. Bring tables. Some people have even brought portable computer databases. They are valuable. Bring photographs of your devices and explant analyses. Data that have been collected but are not brought to the meeting could be considered as damaging information that is purposely withheld. If you bring it, there is a good chance it may be favorably interpreted.

Here is one final word about labeling. Do not make sweeping statements or claims about how this device would work in everybody. Be specific. Do not try to advertise in the product literature. Such advertising is going to eventually be deleted anyway. The intended target group in the product labeling must match the PMA study group. Do not add a few extras on there so you can increase your potential market. We will restrict it to the group studied in the IDE.

It is important to illustrate and carefully explain to novice operators how to properly use the device. Rely on illustrations, and make sure that you put plenty of cautions and warnings for things that were detected during the clinical trial. Update that labeling for things that have been identified in the trial.

Now I will make one final comment about the panel itself. We receive a very large amount of documentation with only a few weeks to review it. Try to keep it organized. It is my preference that the agency limit the size of the submission to 50 pages or less. We have seen tremendous redundancy in these applications. Every other page restates the same thing, and often it restates claims of effectiveness. We will make up our minds if we think it is effective or not. So avoid too much advertising in the PMA, too many global claims of effectiveness, and boil it down because the reading burden is tremendous.

MODERATOR HILL: Thank you very much. That is a wonderful, practical summary of the whole process. Are there any questions right now directed toward it?

MR GLEN A. RAHMOELLER (Arlington, VA): Does the guidance that Ms Lemperle described in her presentation this afternoon reflect also the panel's views on what should be in the applications? That is, has the panel reviewed in detail the guidance that Ms Lemperle described?

DR LEVINSON: The guidance that I referred to is several years old. Ms Lemperle has summarized opinions

and decisions that have taken place inside the FDA, but I am not aware that they have been formally printed in the Federal Register. Is that correct?

MR RAHMOELLER: That was not my question. My question was, has the advisory committee reviewed the guidance that Ms Lemperle described? Is this a reflection also of the advisory committee's views on this subject, or is this something that has been developed within FDA without formal review by the advisory committee? That was the question.

DR LEVINSON: I am going to defer to Ms Lemperle. I have not seen this work inside the agency. I believe it is developed inside the agency.

MR RAHMOELLER: I think it is an important point because initially the advisory committees were set up to provide medical input to the agency, and in fact the medical device advisory committees until the most recent law differed from the drug advisory committees because the medical advice advisory committees were required to review applications—it was not at the FDA's discretion. From my input I think it is important to make sure that the physicians on the advisory committees have input to these types of guidance that are reflected in IDEs and deficiency letters that go to the industry.

MS LEMPERLE: When the guidance document was developed it was circulated to everybody, to our panel for their input, to industry for their input, and to all the physicians and all the committees. I have updated it to some degree in what I gave you today. But essentially it is the same thing that was put together early in 1988.

DR O. H. FRAZIER (Houston, TX): Who selects this panel, Dr Levinson? How is this panel arranged that you are on?

DR LEVINSON: I do not know who the individuals are who select the panel. It is done inside the agency itself. I was contacted by Bill Letsing at that time. He has left, and there have been a number of changes in personnel. But when there is a particular need, the devices division invites consultants who do not have an obvious conflict of interest financially with companies and who have experience in the area they need. Usually those individuals sit on one or two sessions, and if they are of the right level of experience they may be invited to sit as a voting member for subsequent meetings. Now Dr Abhijit Acharya is here and Dr Acharya has the central role in that section, so I might defer the rest to him.

DR ABHIJIT ACHARYA (Rockville, MD): The advisory panel members rotate on and off. Usually they serve about two to four years, so when there is a vacancy we publish it in the Federal Register asking for nominations from interested parties. We occasionally get nominations from professional societies and others. A lot of times we do not get any response at all from the Federal Register. I suspect

that you all do not read Federal Registers. I do not blame you. At that point, we use our informal contacts with physicians currently on the panel and physicians we know of from meetings and professional societies and request participation. Because the circulatory assist system panel has to be balanced between electrophysiologists, cardiologists, and cardiac surgeons, we do look for those specialties when a particular vacancy occurs with an eye to the proper balance.

SPEAKER: What is the number of people on the panel?

SPEAKER: It is seven working members plus there is an industry representative and a consumer representative.

SPEAKER: So it can be just nominated from the field, basically. It is not a professional.

DR FRAZIER: One thing that has concerned me for a long time is the inclusion for chronic heart failure patients of the acute failure circulatory data that Jack Norman generated in the 1970s. Probably 20% of our patients who are outpatients awaiting heart transplantation have cardiac indexes of less than $2 \text{ L} \cdot \text{min}^{-1} \cdot \text{m}^{-2}$. And as I showed you today, I had three young people die in August who died of chronic heart failure. The oldest one was 44 years old without ever reaching these criteria. Do you know of any mechanism by which that criterion, which is inappropriate for this patient group but has hung on from the 1970s, can be changed?

SPEAKER: I was listening to the presentation of those patients and I had the exact same impression. From my particular perspective I felt those patients should have received implants and been treated as outliers in the analysis.

DR FRAZIER: Well, I cannot do that because I have already been informed by the FDA if I ever do that again I cannot do any more research in a field that I have worked in since 1964.

DR ACHARYA: I think in handling that the only particular way you can do that is to attempt to redefine those criteria and submit them as a protocol addendum. Virtually change the protocol. Because you have found that the inclusion criteria are too restrictive. You have patients who need the service who are otherwise candidates according to the 1991 viewpoint, and you have to amend the protocol. I am sure that discussion will be difficult, but that, I think, is the way it has to be handled.

DR FRAZIER: But to who? To where? I have been trying to hit it for years now, and I have been unsuccessful. So I do not know how to deal with it.

MS LEMPERLE: We have been in contact in the past with the circulatory committee. We have talked about admission criteria, and we are open to talking to them

again. We would be very happy to. We welcome discussion on this.

DR FRAZIER: Well, if we could get to the committee somehow, I think we have the data. But I am not sure exactly how to do that. But you would say to write some sort of addendum and the committee could investigate it, perhaps.

DR ACHARYA: Let me just throw this out. It is a suggestion. I think if you feel that these criteria are too restrictive and you are losing good-quality candidates, submit a protocol addendum and ask for it to be sent to the physician panel. I think that I would support personally expansion of criteria if the limitation you are having is cardiac index or blood pressure, because we have all seen patients who do not fit each and every single one of those but are still candidates for a device. If you feel that you can expand it and give it in some written format to us, I would be more than happy to review it and recommend to the agency that they expand that protocol.

DR FRAZIER: Thank you.

SPEAKER: Ms Lemperle, does this type of modification restart the clock on an application for a device? That is the sense that I get with the murmurings around the room; that while the doctors want to change the criteria the industrial people want to keep them the same so we can get them to market.

MS LEMPERLE: That is correct. If you are going to change the criteria you are going to change the study and it will mean new patients entering in the study, or expanding the study.

SPEAKER: That is a difficult catch-22.

DR FRAZIER: This is so even if you can show that the criteria are incorrect in 1991? Is that science? Because we can easily show that.

MS LEMPERLE: We would be delighted for you to present something that we could review.

DR FRAZIER: That is not science, and we all know that is not. This is absolutely crazy, this cardiac index thing.

MS LEMPERLE: I think you are trying to answer two different questions here. I think the second question that was brought up is, if the criteria are changed, does that restart the clock? And I suspect that it would restart the clock for that group of patients. The other group of patients, if they were large enough to be examined would be examined, and they would stand on their own. Is that correct?

DR ACHARYA: Yes. That is how I would look at the final submission. I think that if you change those criteria and you do it across all the centers in the study and they adhere to the new criteria, then you simply form a group

1 and a group 1A and they can fall out in analysis. You might have to go from 50 patients to 65 to get through, but I do not think you have to start at zero with a whole new study. That is one value in trying to get the physicians on the panel to look at these new criteria and see if they will basically approve these inclusion criteria and then analyze the group as a whole and then the two subgroups. Chances are that as you loosen up the criteria as you describe you are going to increase the number of patients and make the trial move along. I would still support this particular trial you are referring to with the expanded criteria. I do not think you have to start at ground zero for it.

DR FRAZIER: We can belabor this probably too much, but I am not talking about loosening up the criteria. I am talking about making the criteria medically and scientifically appropriate to the patient group we are studying or attempting to study. It is not a loosening up. It is just simply righting something that is off keel. I would not want it to be misinterpreted; in fact it might in some ways narrow the criteria. But it needs to be scientifically directed toward what causes death in the chronic heart failure patient awaiting a heart transplant, which is totally different than the patient with an acute myocardial infarction or the patient with failure to wean after cardiectomy. It is a different patient group. Whereas we have criteria that are for that patient group. I would not want to be viewed or to be thought of as supporting something just because we want to do more. I want to make it more focused in a scientific way toward the patient group that we are addressing.

DR ACHARYA: Let me summarize what I think I heard. First of all, if you are going to have entrance criteria and start a study group, the time to establish that is at the beginning. Correct? Second, I think that you have indicated that the FDA and the panels are receptive to rediscussing these entrance criteria for a defined group of patients whether they be myocardial recovery, bridge to transplantation, or permanent, that these could be rediscussed if they are properly outlined and presented back to the FDA and to the panel. Did I understand that right?

DR LEVINSON: They will be discussed. I think members of the panel feel that these protocol amendments are normal behavior as long as they are handled in a scientific fashion. I cannot speak for the regulatory people inside the agency. I will have to ask Ms Lemperle if she agrees.

DR ACHARYA: This has been a very sticky point over a long time. I think it does illustrate the difference between the physicians who practice, physicians who have run studies like this before, and the regulatory people. That is why this panel does exist.

MS LEMPERLE: I think it would take a lot of discussion to go over the issues, because I think Dr Frazier is referring to a study that has already had its protocol changed, and it is established the way it is now for a

specific reason. I think that if the protocol was changed again it would take a lot of thought and consideration between the sponsor and the FDA with his input and the input of other investigators in it. I certainly would not want to make a decision about that now. We would be willing to discuss it, but it would undoubtedly prolong the study.

DR ACHARYA: But as a matter of practice, if brand X came along and they had some sort of device that they wanted to introduce into a certain patient group, the entrance criteria for those group can be discussed and negotiated to be realistic for medicine for 1999—for 1991.

MS LEMPERLE: Yes. You could have a separate patient group that could be studied under the IDE. You would look at that group separately, while you are continuing to study the other group.

DR ACHARYA: That is what I mean. Or even an entirely new device. There are more devices in the minds of these people here, and they want to know that when the time comes to go out of their animal studies into humans the entrance criteria that they can work with possibly may not be the same historical ones that have existed, if it makes sense to change them.

MS LEMPERLE: That is correct.

MODERATOR HILL: I think we will move on, unless you have something else to add.

DR ACHARYA: There are trials that do not have historical inclusion and exclusion criteria. They have to be made up for that device as it enters the market. There are some devices that do not have history behind them and do not have the Norman criteria. So the sponsor has to generate those based on the medical indications he thinks are appropriate and the types of patients that he thinks he is going to serve, and firm those down. I think the FDA has always supported the sponsor defining those.

MODERATOR HILL: Well, we have heard from two of the advocates of society that are trying to support our patients, and now we will hear from another important one, industry. Victor Poirier is here from Thermo Cardio-systems to represent their point of view and their advocacy.

MR POIRIER: It takes the cooperative effort of three independent groups, all working together, to achieve success in making a life-saving technology available to a patient. As shown in Figure 1, each group shares in the common concern of patient safety, patient well-being, and device efficacy. Industry, however, has an additional concern, and that is survival—not the patients' survival, but the company's survival.

Industry is always positioned between the physician and the FDA. The physicians' primary concern is with the patients' well-being. It is their responsibility to address

CLINICAL STUDY

Patients' Well-being

TCI

Fig 1. Three independent groups required for a study.

issues of patient care, patient selection, and study protocol. The industry's primary concern is how can it best carry out this study to satisfy FDA requirements while satisfying the physicians' primary concern of patient survival. This discussion addresses industry's concern about study protocol and FDA requirements and how these affect company survival.

Unlike the physician and the FDA, industry must be concerned with its survival. Several companies have come and gone in this field because of the difficulty in getting a device to market. This difficulty is not necessarily of a technical nature, but of a business nature. These difficulties reduce to a consumption of capital and the length of time that capital is at risk. The key is time. Changes in devices, changes in protocol, and delays in approval are all very damaging and can make the difference between life and death to a company.

Our own experience with the HeartMate assist device is a good example of the magnitude of the problem that industry must face. The initial concept of the HeartMate blood pump was in 1975. It took us 10 years, to 1985, before we had sufficient data to submit an application to the FDA for an IDE. After receiving approval, the study was initiated in 1986 and is ongoing. We have submitted our application for commercial approval and hope to receive approval in the very near future. The total time in this case is thus 17 years.

This time-consuming process is also expensive. This process has taken a minimum of 17 years at a cost of approximately \$25 million. This is not a concern with the FDA, nor is it with the physician. It is, however, a major concern for industry. The testing and development time is too long, the risk of investment is too high, the investment is too large, and the payback period is too long. It is clear that this technology would not exist without the initial support from the National Heart, Lung and Blood Institute. Delays can mean the difference between success and failure. Much is left to be learned regarding interfacing this technology to patients. Information is constantly evolving; we are constantly learning things that were not previously known to the FDA, the physician, and industry.

Working with a new technology presents many prob-

lems to all of us, and results in delays. We begin a clinical evaluation with a carefully selected protocol and learn about the device and its interaction with the patient during these early experiences. As a result, we change protocols and lose time. Every day lost and every patient who cannot be counted in the study can result in the failure of a company. Time for industry means expenses. Investors are not willing to wait for a return on their investment that is any longer than they could get elsewhere. Three to four years is as long as an investor is willing to wait. This is a serious problem that industry must face.

Because of the new technology, the FDA is continuously changing requirements and guidelines. There is a significant difference between the amount of data that were required to receive an IDE in 1985 and 1990. Not only were more data required, but the time to obtain the approval was also greater. In 1985, it took 5 months, whereas in 1990 it took 11 months to obtain the approval for a very similar device. How long will it take next time? How can industry schedule time and expenses to accomplish a task when requirements change all of the time?

Testing requirements that are imposed on industry can also be time-consuming and very costly. For example, is it reasonable to base the time that a device is approved for use in a human on animal test data? Animal testing is the most expensive and time-consuming element in the development process. Historically, it has been shown to be impractical to run a series of animals longer than 4 months. Because FDA requirements dictate that animal testing must be conducted to twice the intended duration of use, the longest approval time possible is 2 months. Our clinical experience shows that the average use in a patient is 3 months.

Animal experiments should be conducted to learn as much as possible about biological considerations. Extensive series of at least 8 animals over a specific period is of limited value in predicting clinical performance.

Can we also minimize the in vitro testing requirements before the start of a clinical study? Is it useful to do testing beyond what is necessary to demonstrate that the device is effective? Can in vitro testing be completed during the IDE phase after effectiveness has initially been demonstrated? Can in vitro testing be done in parallel with the clinical study?

Considering that the IDE phase is a continuation of the device testing, do we need to test everything that is required for a PMA before the IDE phase? Do we really need to test at least two times the intended duration at the worst-case conditions? One or the other should suffice, not both. If we do not test everything before the clinical trial, there is, of course, a small risk. Shouldn't the patient make the final decision as to what risk he or she is willing to take? What is the patient risk without the device?

Delays and modifications in devices or protocol are costly. It is expensive to monitor a clinical trial. In our case, to collect data and monitor the clinical study requires one director, two monitors, two data control persons, and part-time statisticians and analysis at a cost of \$500,000 per year, or \$42,000 per month. This is just to monitor the

program and does not include the cost of applications. Every month represents another \$42,000 expense.

Delays can be terminal—one month can make a significant difference to a company or an investor. Delays in adding new clinical sites, delays in approving protocol, and delays in reviewing reports can shake investor confidence and can mean the difference between success and failure of a company. Investor confidence is extremely important for a company.

In summary, industry's perspective is quite different from that of the FDA and the physician. Industry's survival depends on a timely and efficient approval process. Industry must know what the ground rules are and that they will stay firm.

Industry needs FDA guidelines. What are the performance standards? How can we reduce the "back and forth" with the FDA? Can we establish a standard protocol for each patient category?

How can we expedite these clinical studies? We need to have a mechanism to increase the number of study sites to broaden the breadth of our experience. We need to expedite patient entry into the study, and we need to reduce the *initial* in vitro testing requirements without jeopardizing the patient.

The FDA, like industry, must work within a budget. The FDA is underfunded and certainly understaffed. How can the FDA get through everything that is handed to it? The FDA has a tough job to do with limited funds. Industry has a tough job to do with limited funds. Working together is the only answer. We collectively need to be at least as good as our Japanese and German colleagues, who have already approved left VAD systems.

MODERATOR HILL: Do we have any questions from the floor? I think what I got from that is that you are calling for a change. Just for a point of discussion, do you have any specific things that if you had the ability to change you would? You covered the areas, but ultimately anything that is suggested, the test that it has to pass is that the device eventually goes into the patient with the highest knowledge that it is safe and effective—safe for sure; effectiveness maybe to be seen, or partly to be seen. Could you be specific about anything you would suggest to do?

MR POIRIER: Yes. I have been involved with this for many, many years, and we learn every year. We get new information. Certainly patient entry criteria is a hot subject. As Dr Frazier indicated, we established criteria in 1975 between Jack Norman and Bill Bernhard. The criteria are fine for postcardiotomy patients, but they are just not right for chronic congestive heart failure. If we had to start over we would look at different criteria. But at this stage of the game, after seven years into this study, how can we change? We really cannot. Every year that I look at this I have more and more requests for testing on these devices. And I really questioned that in the beginning under an IDE phase. To try to get an IDE phase, is it really necessary to measure time derivative of pressure in blood

pumps if in your animal studies you show that the plasma free hemoglobin level is less than 10 g/dL? Do we really have to do that test? Do we really have to test batteries at 0°C before we get an IDE when the patient is going to be in the hospital all the time? Those are very expensive, time-consuming data. Why can't we do that during the IDE phase? In parallel with the IDE, not before. It just goes on and on. There is a lot of testing that is required of us that is very time consuming and very expensive, and I just wonder when it should be done. It needs to be done before PMA, but maybe it is more appropriate to do it during the IDE phase than before the IDE phase.

MODERATOR HILL: I think everybody has experienced what you called back and forth. There are limited resources at the FDA, and as you know they are burdened with a lot of paperwork, and the industry is also burdened with a lot of things. How could that be tightened up and consolidated?

MR POIRIER: Communications. We need to talk more. The FDA has to understand what our problems are. We have to understand what their problems are. And we have to talk a lot more. I think that is the bottom line. If we understand where we are coming from then I think we can expedite things.

MODERATOR HILL: Are there any comments from the floor on this general area?

DR JOHN LAIRD (North Reading, MA): I wonder what there is for methods or channels of communication between industry and the FDA other than those that are specifically tied to a particular application and questions on procedures and so forth. We have heard about the physicians' position in the matter of the structural component of communication, but where does industry get to talk about the more general issues with the FDA?

MODERATOR HILL: What is the vehicle by which you could possibly bring about the change that has been suggested?

DR LAIRD: My own view is that industry is always in a delicate position. You do not want to raise questions that can somehow jeopardize a particular application you may be dealing with. But there are these very general questions, which have been already described. How can one communicate those? Or how can you get a discussion going about that problem?

MODERATOR HILL: Does the American Association of Medical Instrumentation (AAMI) get involved in this?

SPEAKER: Do they represent industry in this area with the FDA?

MS LEMPERLE: I can ask some of my colleagues if they want to comment on this also. But we do work with AAMI and with the Health Industry Manufacturers As-

Table 1. United Network for Organ Sharing Waiting List—Severity of Congestive Heart Failure (Jan 1990 to Dec 1990)^a

Status	No. of Patients	Died (%)	Received Transplant (%)	Average Wait (days)
I	1,046	295 (28.2)	658 (63)	54
II	1,426	231 (16)	710 (49.8)	303

^a As of October 31, 1991.

sociation (HIMA), and we do work informally with the manufacturers.

SPEAKER: It would be wonderful for me to see the FDA more involved out in the field and seeing these patients. I think it is extremely important to understand what this technology is, and I do not think you can understand what it is unless you really meet with the patients, talk with the patients, and see what their family life is all about. It is not only the patient who is having a tough time here. It is the family also. And as human beings I think we have to consider everything, not only the science but the patients' well-being as well. I would stress that the FDA should put in their budget some money so that they can go out in the field and see these patients and get involved with these patients. They should do a lot more than what is being done.

MODERATOR HILL: Industry in this case should get together and make some suggestions of how they could increase the efficiency; I think that is what we are looking for. This is best done through an official society trying to create a dialogue and to improve both industry's position and the FDA's without increasing the risk to the patient. Through a society, is that the best way to do it?

SPEAKER: We have worked before with the FDA and with the physicians. And I would think that the industry could work with AAMI or HIMA.

SPEAKER: I think it does not matter which group you work with. I think The Society of Thoracic Surgeons is obviously concerned about the physicians. Whether it is Hema or some other group, what has worked best in the past is if all of the manufacturers of a given type will get together and come up with some consensus; that can often have a big impact in dealing with the FDA because they are speaking with one voice.

MODERATOR HILL: We will now go on to the final advocate of the patient and hear from medicine's representative, Bartley Griffith from Pittsburgh.

DR GRIFFITH: My role today is to better define the current status of patients with morbid congestive heart failure so that the counter-poised risk and benefit of prosthetic hearts in the 1990s can be approached contemporarily based on a decade of past experience. In my pursuit of options for these patients, usually by way of cardiac transplantation, I am convinced of the benefits of

currently available "experimental" devices. In the real sense, no one is better able to judge than the patient's real advocate—responsible physicians who are clinical investigators. I believe that far too often patients are lost on the Scylla and Charybdis of rigid safety and efficacy statutory standards applied by nonclinicians, originally written as medical device amendments to the Food, Drug, and Cosmetic Act of 1976. Although the latter was a needed reaction to increasing complexity of devices and was ushered in due to shortcomings of intrauterine devices, pacemakers, and others, the current premarket approval or PMA requirements for ventricular assist devices and artificial hearts are perhaps outdated, and ignore the progress of the last decade in the clinical recognition of imminently lethal congestive heart failure and prosthetic ventricles. The paradox facing the design of experimental protocols for devices intended to treat serious and life-threatening conditions is tied to the Gordian knot uniting valid and ethical science. The more scientific validity of a protocol, the more unethical the design may become. Strict criteria for patient entry, usually coinciding with a prospective control group, provides desirable validity but is ethically unjustified for those excluded with no hope of survival without a medical device. Currently the FDA remains inflexible with regard to patient entry into IDEs, which means manufacturers must deny some patients entry or risk a prolonged and fiscally exhausting wait for PMA. The problem seems to be the malalignment of risk versus benefit of prosthetic ventricles for a population of patients who have fewer alternatives and less likelihood of survival than those patients with the most severe forms of malignancy. It is interesting to look at the FDA's response to the outcry for therapy for those with the eventually lethal human immunodeficiency virus infection. The retroviral drugs, AZT and DDI, went through NDA (the DRN sequent of PMA) expeditiously at 3½ and 6 months, respectively. Precipitate movement of these drugs was due to acquired immunodeficiency syndrome drug priority at the FDA. A similar emphasis should be placed on mechanical blood pumps shown to be effective and reasonably safe for those with severe congestive heart failure. Clinicians alone provide inadequate lobby to force a significant change.

Fig 2. Outcome of 50 candidates dependent on inotropes (1/89 to 11/91). (IABP = intraaortic balloon pump; Tx = transplantation; VAD = ventricular assist device.)

Fig 3. Likelihood of death, transplantation (Tx), or ventricular assist device (VAD) use in 54 intraaortic balloon pump-dependent transplantation candidates (1/89 to 11/91).

To better define the lethality of severe congestive heart failure, I have relied on the large United Network for Organ Sharing (UNOS) database, a snapshot of which in October 1991 showed that of 1,046 UNOS status I candidates listed for transplantation between January and December 1990, 295 or 28% died without a transplant. For those who received a transplant there was an average wait of 54 days. Of interest, a similar number, 231, but lower percentage, 16%, of status II patients died waiting for transplantation, which was performed on average at 303 days (Table 1). In Pittsburgh, 59 transplant candidates who were dependent on inotropes were followed up between January 1989 and November 1991. By three weeks approximately 50% of the inotrope-dependent candidates went on to have an event, 5 died waiting within 60 days, 36 underwent transplantation by 120 days, 8 required an intraaortic balloon pump by 3 months, and 10 needed a ventricular assist device within 40 days (Fig 2). Patients who depend on inotropes are clearly in unstable condition, and given a rather long wait for a donor, are more likely to advance toward lethality than to do otherwise.

A further evaluation of our candidates suggests that those dependent on an intraaortic balloon pump are at a high risk of death or requiring a ventricular device before

Fig 4. Survival after cardiac transplantation by candidate status (1/89 to 11/91). (IABP = intraaortic balloon pump; VAD = ventricular assist device.)

Table 2. Margin of Safety—Candidate Medical Status (Jan 1989 to Nov 1991)

Variable	Wait for Donor Heart			Time to Candidate Death		
	Mean (days)	Range (days)	n	Mean (days)	Range (days)	n
Status II	303 ^a			515		
Inotrope	50	0-325	36	20	1-74	5
IABP	21	0-74	14	16.5	0-46	16
VAD	73	2-144	10	75	5-303	5

^a United Network for Organ Sharing data.

IABP = intraaortic balloon pump; VAD = ventricular assist device.

transplantation (between 1989 and 1991). Sixteen of 54 intraaortic balloon pump-dependent candidates died by 40 days after implantation of the balloon, and most had succumbed before 3 weeks (Fig 3). Of those balloon-dependent candidates who received a ventricular device, most did so within a week. Data provided to me from Drs Frazier and Radovancevic of the Texas Heart Institute confirm the poor survival of intraaortic balloon pump-sustained candidates. The survival of 45 of their candidates averaged 25 days and ranged between 1 and 167. The tendency for our left VAD and routine candidates to have superior rates of survival (Fig 4) is also noted in major registries, including those of The International Society of Heart and Lung Transplantation and the Collaborative Transplant Trial of Opelitz. Combining UNOS data for status II patients with our data for patients who were placed on inotropes, intraaortic balloon pump, and VADs, one can clearly demonstrate the margin of safety or lethality of congestive heart failure (Table 2).

Well, what information do we have relative to the information on the safety of the available experimental VADs that are undergoing IDE scrutiny? Data provided from HeartMate, Novacor, and Thoratec suggest that death after implantation ranges between 35% and 41% and averages 38%. As previously mentioned, the rate of discharge after transplantation is superior to that obtained in patients not supported by a VAD and ranges between 77% and 93%, but averaged 86% (Table 3). Based on the data obtained from the Novacor and Thoratec series, the most common cause of death was multiple organ failure, which was responsible for 32% of those deaths (Table 4).

Table 3. Survival With Ventricular Assist Devices^a

Group	No. of Implant Deaths/ No. of Implants	No. of Hospital Discharges/ No. of Transplantations
Heartmate	18/44 (0.41)	20/26 (0.77)
Novacor	38/94 (0.40)	52/56 (0.93)
Thoratec	53/151 (0.35)	82/98 (0.84)
Total	109/289 (0.38)	154/180 (0.86)

^a Excludes current implants.

Table 4. Cause of Death

Group	Pretransplantation Deaths	Posttransplantation Deaths	
		Predischarge	Late
TAH	3/20: CNS (1), MOF (2)	8/17: mediastinitis (5), rejection (3)	2/9: CAD (1), N. Comp. (1)
Novacor	6/24: MOF (3), AMI (1), CVA (2)	0/18	2/18 CMV (1), rejection (1)
Thoratec	0/1	0/1	0/1

AMI = acute myocardial infarction; CAD = coronary artery disease; CMV = cytomegalovirus; CNS = central nervous system; CVA = cerebrovascular accident; MOF = multiorgan failure.

Other significant causes included bleeding, coagulation disorders, and sepsis. In our experience, these problems were related to advanced congestive heart failure and, thus, late selection. Although these devices pump blood well, they should not be intended for resuscitation heroics. If one wants to look very critically at potential device-related deaths, only right ventricular failure in the case of univentricular support, stroke, and intracerebral hemorrhage could be identified. Obviously, right ventricular failure is not a problem of the device, but again, a problem of patient selection. Not all strokes occur as a consequence of blood that is clotted within the prosthetic ventricle, as preexisting clots may exist within a dilated myocardium, and other intracerebral events usually occurring intraoperatively might, in fact, be based on technical error and not strictly device-related. The point, of course, is that no incidences of mechanical failure of the device have been recorded in any of the major series, and the causes of deaths almost uniformly select late or improper selection as the likely problem. To this end, restrictive protocols relative to patient entry seem to be more the problem than a protection for needy patients.

Finally, I believe something needs to be said relative to the clinical and human dynamic parameters necessary to redefine the most appropriate population to these devices that have already, in my opinion, demonstrated their safety and effectiveness. The initial Norman criteria published in the *Cardiovascular Disease TH1 Journal* in 1975 were left atrial pressures greater than 20 mm Hg, systolic blood pressure less than 80 mm Hg, or cardiac index less than $2.0 \text{ L} \cdot \text{min}^{-1} \cdot \text{m}^{-2}$ and an arteriovenous oxygen difference greater than 10 vol/%. These criteria were

Fig 5. Survival after cardiac transplantation by medical status in a cooperative trial (G. Opelz, 1988-1990).

prepared for patients with acute illness as opposed to cardiac transplant candidates with progressive congestive heart failure. We evaluated a large number of our patients between 1989 and 1990 to determine if there were hemodynamic indices that might predict those who would die of sudden or progressive congestive heart failure. During that period, 37 patients survived to transplantation, 20 died with sudden death presumably with arrhythmia, and 18 died with progressive congestive heart failure. There were no significant differences in any of these three groups of patients in left atrial pressure, which averaged between 22 and 24 mm Hg, cardiac index, which ranged between 1.9 and $2.2 \text{ L} \cdot \text{min}^{-1} \cdot \text{m}^{-2}$, or left ventricular ejection fraction, which ranged between 0.18 and 0.19. I believe that these data make it very difficult for strict reliance on hemodynamic parameters for protocol purposes relative to when a ventricular assist device should be implanted. So much of what we do as physicians involves experience and clinical judgement, which appears to be more valuable than the studied hemodynamic parameters upon which most of the protocols for patient entry criteria are based.

I believe strongly that, from a clinician's standpoint, morbid congestive heart failure represents a lethal disease and those afflicted are at a low risk relative to high benefit for the evaluation of these complicated devices. Ventricular assist device-related mortality is very low compared with problems encountered when patients are selected too late. The outcome of ventricular assist device bridging to transplantation compares with routine and appears better than that obtained for patients supported by inotropes and intraaortic balloon pumps. On behalf of the clinicians who are responsible for these patients, we plead, implore, and demand an appropriate redirection and alignment.

CLASSIFIED ADVERTISEMENTS

Classified advertisements for positions wanted or available must relate only to the thoracic or cardiovascular surgical specialties. Display space (minimum, ¼ page) is also available through Art Carlucci, Elsevier Science Publishing, 655 Avenue of the Americas, New York, NY 10010 (telephone: (212) 633-3806; facsimile: (212) 633-3820). All advertisements are subject to the approval of the editor, and material deemed inappropriate for publication in *The Annals* will be rejected. If anonymity is desired, please indicate this at the time of submission and a code number will be assigned. All responses received will remain confidential in the publisher's office and will be conveyed to the advertiser shortly after receipt. The charge for all classified advertising is **\$1.60 per word per insertion, minimum 20 words**. Abbreviations, dates, initials, post office box numbers, telephone numbers, years, and zip codes are considered one word each. **There is an additional fee of \$25.00 per insertion for box number advertisements.** The copy deadline is 7 weeks prior to publication, eg, for the March issue, copy should be received by the 1st of January. Advertisement orders should be for a maximum of 6 months; advertisements may be renewed for up to 6 months at a time. Advertisement copy should be typed double-spaced and mailed in duplicate to: *The Annals of Thoracic Surgery*, Desk Editorial, Classified Advertisements, Elsevier Science Publishing Co, Inc, 655 Avenue of the Americas, New York, NY 10010 (facsimile: (212) 633-3853). Make *nonrefundable* check payable to Elsevier Science Publishing Co, Inc.

Please note that *The Annals* does not function as a placement service and cannot provide information on advertised positions. When answering advertisements, please write individually to each advertiser you wish to contact, using the address given in the advertisement. To respond to an anonymous advertisement, write to Box Number, *The Annals of Thoracic Surgery*, Elsevier Science Publishing, 655 Avenue of the Americas, New York, NY 10010.

SITUATIONS AVAILABLE

Thoracic and cardiovascular surgeon with emphasis on pediatric/neonate cardiac surgery and cardiac transplantation is needed by a full-service thoracic and cardiovascular surgery group on the west coast. Must have ABTS certification. Excellent salary and benefits package. Please respond with curriculum vitae and case list.

Please respond to Box 702. 702K/D

Cardiothoracic surgeon, board certified/eligible, wanted to join established practice in northwest Indiana (very near Chicago). Excellent salary. Please respond with curriculum vitae.

Please respond to Box 723. 723L/G

Board eligible or certified cardiovascular and thoracic surgeon needed to join a busy practice in the Southeast. Excellent salary and fringe benefits leading to partnership.

Please respond to Box 737. 737H/A

Cardiothoracic vascular surgeon, board certified or board eligible, to join well-established, busy one-man private practice in Midwest. Salary leading to partnership. Please send CV and references.

Please respond to Box 743. 743A/L

BC/BE cardiovascular and thoracic surgeon wanted to join busy two-member group in Fort Lauderdale, Florida. Recent US medical graduate preferred.

Please send CV to I. Tabry, MD, 2773 NE 37th Drive, Fort Lauderdale, FL 33308 ((305) 561-9781 after 9:00 PM). 746H/A

Cardiothoracic and vascular surgeon, board eligible or certified, to join 2-man private practice in Ft. Lauderdale, Florida.

Please send CV to Salem M. Habal, MD, 4800 NE 20th Terrace #107, Ft. Lauderdale, FL 33308; (305) 771-3220. 748H/A

Thoracic/cardiovascular surgeon: three-man group in suburban New York doing general thoracic and peripheral vascular surgery desires new graduate of approved thoracic program with training in vascular surgery. Please respond with CV.

Please respond to Box 758. 758I/B

Cardiovascular and thoracic surgeon: BE/BC wanted to join an established, busy private practice in the Midwest. Peripheral vascular expertise desirable. Recent graduate of a university program preferred. Salary leading to full partnership. Please respond with curriculum vitae and references.

Please respond to Box 763. 763I/B

Cardiothoracic surgeon—BE/BC—to join 2-man practice in South performing adult cardiac, thoracic, and vascular surgery. Surgeon finishing training or recent graduate preferred.

Please respond to Box 770. 770J/A

Cardiothoracic surgeon, BE/BC, to join busy 1-man private practice in mid-Michigan. Excellent opportunity. Salary leading to partnership. Please send CV and references.

Please respond to Box 779. 779J/C

Cardiothoracic surgeon needed to join established 2-man group in practice of adult cardiac, pulmonary, and vascular surgery. Must be board certified or eligible and graduate from a US medical school.

Please respond to R. W. Ruess, MD, 1834 Broadway, Cape Girardeau, MO 63701. 788K/A

Noncardiac thoracic surgeon wanted to join a group in northern New England. The practice would involve thoracic and general surgery. Must be board eligible or certified. Best in rural living. Please send CV.

Please respond to Box 791. 791K/A

Cardiothoracic and vascular surgeon urgently needed to join established practice in Midwest. Applicant must be BE/BC. Salary leading to full partnership. Please send CV and details of experience.

Please respond to Box 792. 792K/A

Thoracic and vascular surgeon, BE/BC, to join active (noncardiac) thoracic and vascular practice in central New Jersey. Please respond with curriculum vitae and details of experience. Salary leading to full partnership.

Please respond to Box 795. 795K/C

Cardiovascular and thoracic surgeon: Excellent opportunity for a board certified/eligible university-trained surgeon to join a new, growing department in a metropolitan New York community. Academic/private practice setting with excellent compensation. Experience in electrophysiologic surgery, artificial devices, and transplantation helpful. Please respond with curriculum vitae.

Please respond to Box 799. 799L/E

University of Florida seeks cardiovascular surgeon to join major teaching unit in Jacksonville, Florida, at University Medical Center. Candidate should be board eligible/certified in thoracic surgery. We seek someone with strong research and teaching interests. Position is tenure-acruing with academic appointment at Assistant to Associate Professor level, depending upon qualifications. Applicant recruiting deadline, April 1, 1993.

Forward curriculum vitae and names/addresses of three references to Eric Ceithaml, MD, Chairman, Cardiovascular Search Committee, University Medical Center, 655 W 8th St, Jacksonville, FL 32209. Affirmative action/equal employment opportunity employer. 801L/A

Cardiothoracic and vascular surgeon, board certified, board eligible to join an expanding three-man practice in the Rocky Mountain region. Please send CV and references.

Please respond to Box 802. 802L/E

Thoracic and vascular surgeon, BE/BC, wanted as associate/partner in private practice with clinical academic appointment in Providence, RI.

Please respond with CV and references to Albert K. Weyman, MD, 100 Highland Ave. Suite 304, Providence, RI 02906.

803L/A

South of Boston: Two experienced thoracic surgeons in very busy private practice offer employment and partnership opportunity for third. Ideal location 20 miles south of Boston offers educational and cultural advantages of an urban environment with options for country or suburban living. Excellent salary and benefit package, leading to full partnership. If BC/BE, please send CV.

Please respond to Box 805. 805L/E

General thoracic surgeon. The Massachusetts General Hospital and Harvard Medical School seek a highly qualified clinician, teacher, and scientist in general thoracic surgery. Training and experience in airway surgery and esophageal surgery required. Appointment would be at the rank of Instructor or Assistant Professor of Surgery at Harvard Medical School, depending upon qualifications.

Please reply with curriculum vitae and bibliography to Hermes C. Grillo, MD, Chief of General Thoracic Surgery, Massachusetts General Hospital, Boston, MA 02114. Harvard Medical School and Massachusetts General Hospital are affirmative action/equal opportunity employers. Women and minority candidates are encouraged to apply. 806L/B

The Division of Thoracic and Cardiovascular Surgery at the University of New Mexico School of Medicine in Albuquerque is seeking applications for a full-time faculty position at the Assistant/Associate Professor level for July 1993. We are looking for an individual with excellent skills in adult cardiac surgery and with specialized training in cardiac transplantation. The candidate must be board eligible or certified and have strong interest in research and teaching. This is an excellent opportunity for an individual interested in academic achievements as well as a good clinical experience.

Please forward curriculum vitae and three letters of recommendation to Jorge A. Wernly, MD, Chief, Division of Thoracic and Cardiovascular Surgery, University of New Mexico Medical Center-ACC2, Albuquerque, NM 87131. An affirmative action/equal opportunity employer. 809L/C

Cardiothoracic surgeon, board certified with 2 to 5 years experience. Wanted for practice in northeastern United States. Practice currently doing 500+ procedures and anticipates growth of 20%. Preferring surgeon with cardiac, thoracic, and vascular. Salary for 2 years, followed by full partnership. Please respond with CV.

Please respond to Box 810. 810L/A

Cardiothoracic/vascular surgeon: board certified in general surgery and BE/BC in thoracic surgery to join strong cardiovascular practice in western Pennsylvania. Major need for thoracic and vascular surgeon; cardiac surgery if desired. Excellent benefits. Detailed CV must accompany response. All replies treated confidentially.

Please respond to Box 811. 811L/E

Cardiothoracic surgeon, BE/BC, for Palm Beach County, Florida, busy, quality two-physician CVT practice.

CV to Kenneth M. Begelman, MD, 1599 NW 9th Ave, Boca Raton, FL 33486; FAX (407) 278-6887. 812L/A

Looking for a compatible cardiac thoracic surgeon with peripheral vascular experience and training. Ideal candidate would have training in electrophysiologic surgery. Southeast PA area. Early partnership offered to right candidate.

Please respond to Box 813. 813A

Cardiovascular thoracic surgeon—board certified/board eligible and recently trained to join an established, busy, dynamic and expanding private practice in northwest Indiana. The sphere of practice is approximately 30 minutes from downtown Chicago. Guaranteed excellent starting salary with progressive future growth and comprehensive corporate fringe benefit program leading to partnership for the right individual.

Write including CV and details of experience and capabilities to PO Box 3066, Munster, IN 46321. 814A/C

Cardiac surgeon to join established, two-man private practice in Chicago and its suburbs. Salary leading to full partnership. Excellent facilities and experienced associates.

If interested, please respond to Box 815. 815A/C

Emory University is seeking applicants for a faculty position in Cardiothoracic Surgery as Assistant Professor. Applicants should have demonstrated productivity in surgical research and be technically strong in all phases of adult and pediatric cardiac surgery as well as pediatric heart and lung transplantation.

Submit curriculum vitae and letters of recommendation to Robert A. Guyton, MD, Chief, Cardiothoracic Surgery, 1365 Clifton Road NE, Atlanta, GA 30322. Emory University is an affirmative action, equal opportunity employer. 816A

Experienced and board certified cardiothoracic surgeon needed to join an established group of thoracic and vascular surgeons in a newly approved cardiac surgery program in a community hospital. Responsibilities include coordinating and leading the cardiac surgical team of this group practice. Competitive package.

Please respond to Box 817. 817A/F

Cardio/thoracic surgeon: Exceptional opportunity for a cardiothoracic surgeon to join same.

Please respond to Allan O. Cook, MD, 4009 Worth St, Dallas, TX 75246; (214) 823-2103. 818A

Cardiovascular and thoracic surgeon, board eligible/board certified, to join a very busy, well-established and expanding private practice in Northeast with medical school affiliation. Excellent salary and benefits leading to partnership.

Please respond to Box 819. 819A

Director—Cardiothoracic Surgery: Board certified cardiac surgeon needed to coordinate and direct a new cardiac surgery program in a community hospital in association with an established group of surgeons. Strong community and medical staff support will assure a successful program. Attractive financial package.

Please respond to Box 820. 820A/F

Noncardiac thoracic and vascular surgeon, BE/BC, to join established one-man private practice on Florida's southeast Gold Coast. Send CV and details of experience.

Please respond to Box 822. 822A/C

Cardiothoracic surgeon: The University of Maryland, Department of Surgery, Division of Thoracic and Cardiovascular Surgery is seeking a cardiothoracic surgeon at the Assistant Professor level. Successful candidates should have training and expertise in cardiac transplantation, laboratory research experience, and a firm commitment to an academic career. Excellent fringe benefit package.

Please send a current curriculum vitae and three professional references to Joseph McLaughlin, MD, Professor and Head, Division of Thoracic and Cardiovascular Surgery, Department of Surgery, University of Maryland, c/o Lois Reisig, Department of Surgery, 5th Floor, 405 W Redwood St, Baltimore, MD 21201. EOE/M/F/H/V, minorities and females are encouraged to apply. 823A

Thoracic and vascular surgeon, BC/BE, needed for community practice in Northeast. No cardiac surgery. Please send CV.

Please respond to Box 824. 824A/B

Cardiothoracic and vascular surgeon to join a well-established three-man adult CV practice in California's Central Coast. Applicant must be BE/BC. Recent graduate of university program preferred. Please respond with CV.

Please respond to Box 825. 825A/B

Cardiovascular surgeon wanted to join three surgeons in an established adult cardiac, thoracic, and vascular surgery practice in north central Texas. Must be board certified/eligible. Salary plus benefits with full partnership available. Please send resume and references.

Please respond to Box 828. 828A/C

Junior or senior level position, thoracic and cardiovascular surgery: The Department of Surgery of the University of Wisconsin-Madison Medical School is recruiting a faculty member in the Division of Thoracic and Cardiovascular Surgery with an interest in a range of clinical, teaching, and research responsibilities. This position requires specialization in thoracic and cardiovascular surgery.

Applicants should submit resumes by January 30, 1992, to Robert M. Mentzer, MD, Chairman, Division of Thoracic and Cardiovascular Surgery, University of Wisconsin-Madison Medical School, Room H4/358 Clinical Science Center, 600 Highland Ave, Madison, WI 53792-3236. The University of Wisconsin is an affirmative action/equal opportunity employer. 831A

Faculty/academic position: The Division of Cardiothoracic Surgery, University of Washington, is seeking a BC/BE, adult cardiothoracic surgeon. The individual will have a dual appointment at University Medical Center and the Veterans Administration Medical Center. He/she will be responsible for continuing the VA clinical, educational, and research programs. He/she should have demonstrated a strong clinical cardiac surgery background and commitment to education and research. AA/EOE.

Send complete curriculum vitae to Edward D. Verrier, MD, Division of Cardiothoracic Surgery, RF-25, University of Washington, Seattle, WA 98195. 834A/B

General thoracic surgeon, BE/BC, wanted to join private practice at university-affiliated teaching hospital. Strong background in peripheral vascular surgery desirable. Location in Northeast suburban area. Excellent opportunity.

Send CV to Dr Charles Sills, Program Director, Monmouth Medical Center, 300 Second Ave, Long Branch, NJ 07740. 835A

Academic general thoracic surgeon: The Division of Cardiothoracic Surgery and the Section of Thoracic Surgery invites applications and nominations for a faculty position in general thoracic surgery at the University of Washington. Prospective candidates should be American Board of Thoracic Surgery eligible or qualified as of July 1, 1993, have demonstrated excellence in clinical surgery and research, and possess a commitment to teaching. Preference will be given to those who have broad experience in general thoracic surgery including lung transplantation. The successful candidate will be involved in the clinical programs at the University of Washington Medical Center, Harborview Medical Center, and Seattle Veterans Administration Hospital in Seattle as well as becoming actively involved in the Lung Transplant Program, the Cardiothoracic Surgery Laboratory, and in participating in the Thoracic Surgery clinical trials.

Applicants should have their curriculum vitae sent to the following address: Douglas E. Wood, MD, Chief, Section of Thoracic Surgery, University of Washington, Division of Cardiothoracic Surgery, SA-25, Seattle, WA 98195. University of Washington is an equal opportunity, affirmative action employer. 836A/B

SITUATIONS WANTED

General thoracic surgeon (BC), mature, looking for community with need, preferably Northeast or Southwest and group practice. Recent 10 years general surgical experience (BC) including laparoscopy.

Please respond to Box 741. 741H/A

Cardiothoracic surgeon, 35 years old, university trained, board certified with two years busy private practice experience. Seeks opportunity with new program, individual, or group in the Southeast.

Please respond to Box 757. 757J/C

General thoracic and general surgery combined. Board certified. Recent graduate looking for an exciting practice. Interest in endoscopic and laser surgery.

Please respond to Box 790. 790K/D

56-y.o. Thoracic and cardiovascular surgeon, American graduate, university trained, numerous publications, advanced surgical degree. Recent 3 + 6 months tutorial in vascular and general surgery. Wishes to relocate.

Please respond to Box 794. 794K/A

Excellent training in all aspects of adult cardiovascular and thoracic surgery including heart and lung transplantation. Extensive prior experience in the specialty in England. Seeks opportunity with private or academic group practice. Available July 1993. CV and references upon request.

Please respond to Box 796. 796K/A

Cardiothoracic surgeon, ABS, ABTS eligible, desires position with busy cardiothoracic group. Can assist or operate, considerable thoracic and ICU experience.

(504) 868-9358. 800L/A

FELLOWSHIPS

Surgical residents/fellows—Clinical residency/fellowship positions available in adult and pediatric cardiothoracic surgery. Large volume of cases. New Jersey license required. Excellent salary and benefits.

Please contact Lynn B. McGrath, MD, Chairman, Department of Surgery, Deborah Heart and Lung Center, 200 Trenton Rd, Browns Mills, NJ 08015; (609) 893-6611, Ext 359. 653A

Fellowship in adult cardiac surgery beginning July 1993 and available for one or two years in private program performing over 600 open heart procedures yearly. Cardiac surgery training required. ECFMG and visa qualified foreign applicants accepted.

Send curriculum vitae to Donald R. Kahn, MD, 817 Princeton Ave, Suite 300, Birmingham, AL 35211. 786K/A

Fellowship in a very busy pediatric cardiovascular surgery center is available July 1993. Experience includes performing surgery for very complex congenital heart disease and participation in ongoing educational and research activities. Illinois license or equivalent required. Salary and benefits exceed \$45,000.

Please respond to the Division of Pediatric Cardiac Surgery, The Heart Institute for Children/Christ Hospital and Medical Center, 4440 West 95th St, Oak Lawn, IL 60453. 821A/B

Cardiovascular surgical fellow: Department of Cardiovascular Surgery, San Francisco Kaiser-Permanente Medical Center, offers a one-year clinical fellowship in cardiovascular surgery beginning July 1, 1993. Applicants must be ABS BC/BE. High volume, excellent salary and benefits.

Please send CV and direct questions to M. Terry McEnany, MD, Chief, Department of Cardiovascular Surgery, Kaiser-Permanente Medical Center, 2350 Geary Blvd, San Francisco, CA 94115; (415) 202-3800. 826A/D

Cardiothoracic surgical fellowship—Allegheny General Hospital is seeking qualified candidates for a one-year, nonaccredited fellowship position in cardiothoracic surgery, available July 1, 1993, through June 30, 1994. The program enjoys a large volume of adult cardiac surgery and thoracic surgery cases, including thoracoscopy, esophageal and pulmonary resections, in addition to a strong research program. The program is assisted by seven physician assistants.

Please send a CV and letters of recommendation to George J. Magovern, MD, Professor and Chairman of Surgery, Allegheny General Hospital and the Allegheny Campus of the Medical College of Pennsylvania, 320 E North Ave, Pittsburgh, PA 15212. 827A/D

Cardiothoracic surgical fellowship. Available July 1, 1993, to June 30, 1994. One year noncredited appointment available to persons completing general surgery residency to assist in the

preop management, surgery, and postop management of cardiothoracic surgical patients.

Submit complete curriculum vitae to John C. Baldwin, MD, Professor and Chief, Cardiothoracic Surgery, Yale University School of Medicine, 333 Cedar St, PO Box 3333, New Haven, CT 06510. Yale University is an affirmative action/equal opportunity employer. 829A

Cardiopulmonary transplant fellowship. Available July 1, 1993, to June 30, 1994. Active transplant program offers surgeon opportunity to assist in donor procurement, operations, preop and postop management of patients, as well as recipient evaluation. Position is appropriate for person who has completed general surgery residency, those awaiting cardiothoracic surgery residency, or for surgeon who has completed thoracic surgery and is seeking additional transplant experience.

Submit complete curriculum vitae to John C. Baldwin, MD, Professor and Chief, Cardiothoracic Surgery, Yale University School of Medicine, 333 Cedar St, PO Box 3333, New Haven, CT 06510. Yale University is an affirmative action/equal opportunity employer. 830A

Cardiothoracic research fellowship: The Division of Cardiothoracic Surgery at the University of Washington is seeking research fellows for 1-2 years. Active lab research interests include the vascular and molecular biology of ischemia/reperfusion, heart/lung transplantation, and myocardial protection. Surgical residents preferred, prior research experience not required.

Interested applicants should send CV to Ed Verrier, MD, Associate Professor and Chief, Division of Cardiothoracic Surgery, SA-25, University of Washington, 1959 NE Pacific Ave, Seattle, WA 98195. 832A/B

Senior fellow position available for 1 year: Cardiothoracic surgical residency program has 1-year fellowship at senior level to begin July 1, 1993. High-volume program offers excellent experience in electrophysiologic surgery, valve repair, cardiac transplantation as well as standard cardiac surgical procedures. Salary equivalent to senior cardiac resident level.

Apply to Edward D. Verrier, MD, Chief, Cardiothoracic Surgery, University of Washington Medical Center, Department of Surgery, SA-25, Seattle, WA 98195, USA; (206) 685-3370. 833A/B

Chairman and Professor, Cardiothoracic Surgery

*Tufts University School of Medicine
New England Medical Center Hospitals*

Applications are invited for the position of Professor and Head, Division of Cardiothoracic Surgery, Tufts University School of Medicine, and Chairman, Department of Cardiothoracic Surgery, New England Medical Center Hospitals. We seek a candidate with the highest academic credentials who will be able to direct a vigorous multi-faceted department in an expanding academic Medical Center and leading Medical School.

Please send your curriculum vitae and supporting information to Deeb N. Salem, M.D., Chief, Cardiology Division, Department of Medicine, New England Medical Center Hospitals and Tufts University School of Medicine, 750 Washington Street, NEMC #79, Boston, MA 02111-1845. An Equal Opportunity Employer.

New England Medical Center

Assistant Professor Cardiothoracic Surgeon

The Division of Cardiothoracic Surgery at the University of Massachusetts is expanding its academic faculty. Candidates will be expected to have an interest in developing an academic cardiothoracic practice, to participate in thoracic and general surgical residency training, and to take part in clinical and/or laboratory research.

The University of Massachusetts is an equal opportunity employer.

Please respond with curriculum vitae to: **Thomas J. Vander Salm, M.D., University of Massachusetts**

**Medical Center,
55 Lake Avenue North,
Worcester,
MA 01655.**

Cardiothoracic Fellow

The Lankenau Hospital and Medical Research Center is a state-of-the-art medical teaching and research facility nestled in a beautiful, yet convenient suburban Philadelphia location. This past year we performed over 800 open heart surgeries including surgery for atrial and ventricular arrhythmias.

We will have a position available July 1, 1993 on our staff for a Cardiothoracic Surgical Fellow. The ideal candidate should be board eligible or certified in general surgery. Board eligible in thoracic surgery highly desired. A Pennsylvania license is a must. Clinical Fellows are welcome to apply.

Along with top of the line technology and professional colleagues, the position offers medical benefits, no city wage tax deducted and a non-smoking environment. For further information, please forward CV to: Dr. Scott M. Goldman, Chief, Division of Thoracic & Cardiovascular Surgery, c/o Personnel Department, 100 Lancaster Avenue, west of City Line, Wynnewood, PA 19096.

TRENDS IN Cardiovascular MEDICINE

Trends in Cardiovascular Medicine keeps you up-to-date with advances in cardiovascular research that will have important diagnostic and therapeutic implications.

Each issue features six to eight brief reviews of key topics at the vanguard of cardiology. Because clinical advances are often based on experimental observations, **Trends** authors discuss how developments at the lab bench today can influence the practice of bedside medicine tomorrow.

Topics covered by **Trends in Cardiovascular Medicine** include:

Case Studies in Human Genetics

- lipoprotein(a): bridging atherosclerosis and thrombosis
- clinical and molecular genetics of hypertrophic cardiomyopathy
- new insights into genetics of long QT syndrome
- recent advances in viral myocarditis

Emerging Technologies

- the polymerase chain reaction (PCR) and the diagnosis of cardiovascular disorders
- NMR spectroscopy for the study of the biochemistry of the cardiovascular system

Brief Reviews

- strategies for gene therapy using endothelial cell and recombinant animal virus vectors to achieve gene transfer
- new directions in thrombolytic therapy, including the genetic engineering of novel t-PA molecules and other important recombinant proteins
- gender and cardiovascular disease

Trends in Cardiovascular Medicine's

editor-in-chief and executive editors select these topics and their authors, all highly regarded individuals in the area under review. Moreover, all articles are subject to peer-review, ensuring accuracy in presentation.

Trends in Cardiovascular Medicine can help you understand how today's research will change tomorrow's clinical practice.

THE ANNALS OF THORACIC SURGERY

*Official Journal of The Society of Thoracic Surgeons
and the Southern Thoracic Surgical Association*

Elsevier

SOME KNOW US FOR THE PACE WE'VE SET

It's not surprising that much of the medical community knows Medtronic as "the pacemaker company." We've worked hard to bring effective pacing therapy to physicians and their patients. As a result, we've become the worldwide leader in pacing -- not just in sales, but in innovation, service and education.

BUT OUR CIRCULATION IS MUCH WIDER

But some are surprised at the depth of our commitment to cardiovascular surgery. For over a decade we've produced innovative blood handling and valve technologies that benefit surgical teams and their patients. And our Cardiovascular divisions are also worldwide leaders in sales, service and education. Don't be surprised if more people start calling Medtronic "the cardiovascular surgery company."

The GORE-TEX® Surgical Membrane was removed after ten months implant duration. No epicardial reaction was noted and an effective plane of dissection was provided. Photo courtesy of S. Subramanian, M.D.

Proven Reoperative Reliability*

The GORE-TEX Surgical Membrane was removed after two months implant duration. The coronary vasculature is visible and there is a lack of adherent tissue. Photo courtesy of H. Lindberg, M.D.

An Open And Closed Case

Epicardial/mediastinal adhesions are a critical reoperative challenge, at times leading to serious inherent problems such as:

- Cardiac Damage
- Catastrophic Hemorrhage
- Increased Dissection Time

Since 1976, the GORE-TEX® Surgical Membrane material has been the only pericardial substitute to consistently facilitate cardiac reoperation by providing a reliable plane of dissection and reducing adhesion formation. This minimizes the risk of:

- Cardiac Damage
- Catastrophic Hemorrhage
- Increased Dissection Time

For further information, including current available literature and recommended implant techniques, call 800-437-8181, Dept. 6-N. To order call 800-528-8763, Dept. 6-N.

*A new look at
biocompatibility.
Bentley® Duraflo® II.*

Every part of the perfusion circuit creates an environment that is hostile to your patient's blood. This hostile environment disrupts the integrity of the vascular system and stimulates blood reactions – including coagulation – which can routinely effect your patient's recovery.

Blood reactions can effect your patients' postoperative recovery

That's where Duraflo® II can help. By binding whole USP heparin directly to every blood contact surface, we've created a biologically active barrier between the foreign surfaces of the circuit and your patients' blood.

Duraflo® II creates a biologically active barrier between blood and foreign surfaces

What's more, Bentley is the only cardiopulmonary company able to provide cannula-to-cannula biocompatibility – even on cardiotomy reservoirs. This universal protection turns a hostile environment into a friendly one, and that can mean fewer complications and faster recoveries for your patients.

Universal biocompatibility protection can mean fewer complications and faster recoveries

To give your patients this kind of protection, just ask your Bentley representative about the All-In-One Tray GOLD™ BosPac®. Or call for information at (800)BEST-PAC, and see why Duraflo® II is the new GOLD™ standard-of-care in perfusion.

Duraflo® II is the new GOLD™ standard-of-care in perfusion

At Bentley, everything we touch turns to GOLD™.

An invitation for current subscribers

Bound Volumes of **THE ANNALS OF THORACIC SURGERY**

Reserve your 1992 bound volumes now! As a special service to current subscribers only, **THE ANNALS OF THORACIC SURGERY** is available in bound volumes, priced at \$90.00 (US) and \$110.00 (International). The two volumes for 1992 (Volumes 53 and 54) are bound in blue buckram—the same high quality binding you would find in a library—with stamped lettering on the spine. These handsomely bound volumes include:

- complete author and subject indexes
- editorial content only, with all advertising removed
- sturdy bindings for durable reference

From now on, when you receive your regular monthly copy of **THE ANNALS OF THORACIC SURGERY**, don't hesitate to tear out or mark up articles of particular interest. These specially bound volumes include every issue in perfect condition to help you keep your personal library complete, organized and current.

Reserve your 1992 bound volumes by returning the order form below.

Clip and mail to: Elsevier Science Publishing Co., Inc. PO Box 882, Madison Square Station, New York, NY 10159

ORDER FORM

☐ Please send me bound volumes 53 & 54 for **THE ANNALS OF THORACIC SURGERY**.* Both volumes will be shipped together for a total cost of \$90.00.

☐ Please send me bound volumes 51 & 52 for **THE ANNALS OF THORACIC SURGERY** from 1991. Both volumes for \$90.00

Outside the US, please add \$20.00 for postage and handling.

☐ Please start my annual standing order to receive bound volumes of **THE ANNALS OF THORACIC SURGERY**. Two bound volumes automatically will be shipped together at the end of each year.

Note: *Offer available only for subscribers to **THE ANNALS OF THORACIC SURGERY**. Please allow 3-5 weeks for receipt of your bound volumes.

Please return to:
Elsevier Science Publishing Co., Inc.
P.O. Box 882
Madison Square Station
New York, NY 10159

GENERAL INFORMATION *The Annals of Thoracic Surgery* is indexed/abstracted in *Index Medicus*, *Current Contents/Clinical Practice/Life Sciences*, *Excerpta Medica*, *Reference Update*, and *Biological Abstracts*.

Please direct orders for subscriptions, single copies, and back issues; changes of address; and claims for missing issues to: Journals Fulfillment Department, Elsevier Science Publishing Co, Inc, 655 Avenue of the Americas, New York, NY 10010. Claims for missing issues can be honored only up to 3 months for domestic addresses, 6 months for foreign addresses. Duplicate copies will not be sent to replace ones undelivered through failure to notify Elsevier of change of address.

The Annals of Thoracic Surgery (ISSN 0003-4975) is issued monthly in two indexed volumes per year by Elsevier Science Publishing Co, Inc, 655 Avenue of the Americas, New York, NY 10010. Printed in USA at 2901 Byrdhill Road, Richmond, VA 23228. Subscription prices per year: Institution: \$185.00; individual, \$102.00; interns and residents, \$57.50. Outside USA, add \$38.00 for surface postage and handling. For air delivery to USA, Canada, and Mexico, add \$85.00; to Europe, \$75.00 (via surface airlift); to Japan, \$95.00; and to the rest of world, \$170.00. Second class postage paid at New York, NY, and at additional mailing offices. Postmaster: Send address changes to *The Annals of Thoracic Surgery*, Elsevier Science Publishing Co, Inc, 655 Avenue of the Americas, New York, NY 10010; telephone (212) 989-5800.

Microfilm copies are available through University Microfilms International, 300 North Zeeb Road, Ann Arbor, MI 48106.

Reprints, except special orders of 100 or more, are available from the authors.

Advertising inquiries should be addressed to: Art Carlucci, Elsevier Science Publishing Co, Inc, 655 Avenue of the Americas, New York, NY 10010; telephone: (212) 633-3805 (facsimile: (212) 633-3880).

The publisher assumes no responsibility for any injury and/or damage to persons or property as a matter of products liability,

negligence, or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein. No suggested test or procedure should be carried out unless, in the reader's judgment, its risk is justified. Because of rapid advances in the medical sciences, we recommend that the independent verification of diagnoses and drug dosages should be made. Discussions, views, and recommendations as to medical procedures, choice of drugs, and drug dosages are the responsibility of the authors.

Although all advertising material is expected to conform to ethical (medical) standards, inclusion in this publication does not constitute a guarantee or endorsement of the quality or value of such product or of the claim made of it by its manufacturer.

This journal has been registered with the Copyright Clearance Center, Inc. Consent is given for the copying of articles for personal or internal use, or for the personal or internal use of specific clients. This consent is given on the condition that the copier pay through the Center the per copy fee stated in the code on the first page of each article for copying beyond that permitted by the US Copyright Law. The appropriate fee should be forwarded with a copy of the first page of the article to the Copyright Clearance Center, Inc, 27 Congress Street, Salem, MA 01970. If no code appears on an article, the author has not given broad consent to copy, and permission to copy must be obtained directly from the author. This consent does not extend to other kinds of copying, such as for general distribution, resale, advertising and promotional purposes, or for creating new collective works. All inquiries regarding copyrighted material from this publication, other than reproduction through the Copyright Clearance Center, should be directed to Rights and Permissions Department, Elsevier Science Publishing Co, Inc, 655 Avenue of the Americas, New York, NY 10010; (212) 633-3977.

*To provide a place for ALL thoracic surgeons to relate experiences which
will help other practicing thoracic surgeons give better patient care.*

Herbert Sloan, MD

Think Of It As An Air Bag For Each Vessel.

Our Retract-O-Tape® vascular loop gently and safely stabilizes an anastomotic site. Each loop is made of hollow, silicone tubing sealed at both ends to hold air. During

retraction and occlusion, this flexible air cushion works like an air bag to minimize trauma to vessels and surrounding tissue. With pressure, Retract-O-Tape flattens out enough to properly occlude or retract the vessel, but not so much that it creates flat edges that can cause harm.

A cushion of air protects the vessel during occlusion and retraction.

The patented needle passes easily around the vessel without dissecting surrounding tissue.

The Retract-O-Tape vascular loop also improves visualization in the surgical field. For example, during warm continuous blood cardioplegia, Retract-O-Tape can provide a dry and clear anastomotic site. Consequently, the Retract-O-Tape vascular loop is not only easy on your patient, but also easy on you.

Retract-O-Tape comes in needle and non-needle versions, and are radiopaque and highly visible in the surgical field. The needle versions come in a thin wall, 18 gauge, 12 inch length, while the non-needle versions cover a range of lengths and gauges. No matter what the procedure, Retract-O-Tape can make it go a little smoother. Just as it has throughout the world for the past 15 years.

To receive your free samples, call **1-800-627-0226 Ext. 266** or fax your request to us at 1-214-404-0275 *Attention: Customer Service*. We'll send you a non-sterile loop to examine and a sterile one to use in your next surgery.

Retract-O-Tape is available in a variety of gauges and lengths to meet your needs.

THE ANNALS OF THORACIC SURGERY

INFORMATION FOR AUTHORS

Thomas B. Ferguson, MD
Editor, *The Annals of Thoracic Surgery*
3108 Queeny Tower
Barnes Hospital Plaza
St. Louis, MO 63110-1041
(314) 361-6084 FAX: (314) 367-0585

The Annals of Thoracic Surgery publishes original papers on topics in thoracic and cardiovascular surgery. Also featured are case reports, "how to do it" articles, classics in thoracic surgery, collective and current reviews, correspondence, and book reviews. All manuscripts, correspondence, and editorial business should be sent to the above address. Guidelines for collective and current reviews are available on request.

If a manuscript is accepted for publication, certain conditions must be agreed to by all authors. These include statements regarding conflict of interest, scientific responsibility, exclusive publication, and assignment of copyright. Elsevier Science Publishing Co, Inc, will maintain records of copyright for The Society. No part of the published material may be reproduced elsewhere without written permission from the publisher.

Because of escalating postage costs, manuscripts and illustrations will not routinely be returned to the authors. The editorial office will be responsible for proper disposal of the manuscripts so that confidentiality is preserved. Manuscripts and illustrations will be returned only if requested and a self-addressed stamped (US postage) envelope provided.

Checklist

The following checklist is provided for the author's convenience. Please utilize this list to make certain the manuscript is complete when submitted. Incomplete manuscripts cannot be accepted for editorial review.

General

- ☐ Submit original and *two* duplicate manuscripts (including three clearly separated and labeled sets of illustrations). Retain a fourth complete set as insurance against loss in the mail.
- ☐ Type manuscript double-spaced throughout (including title page, abstract, text, references, tables, and legends) on one side only on 22 × 28 cm (8½ × 11 inch) opaque bond paper with 3 cm (1¼ inch) margins all around. *This also applies to correspondence.* Type the last name of the first author in the upper right-hand corner of each page, including the title page.
- ☐ Arrange manuscript as follows: (1) title page, (2) abstract, (3) text, (4) references, (5) tables, and (6) legends. Number pages consecutively, beginning with the title page as page 1 and ending with the legend page.
- ☐ A manuscript for an *original article* ordinarily should not exceed 26 double-spaced typewritten pages, and should be proportionally shorter the more illustrations and tables that are included.
- ☐ The *text* for case reports should be *no more* than 4 double-spaced typewritten pages. If tables or illustrations are included, the text must be reduced. The text for a "how to do it" article should be even briefer, but with detailed illustrative material. Case reports and "how to do it" articles that exceed the allowable length will not be considered for publication.
- ☐ Referencing should be selective and pertain directly to the work being reported. Except in collective and current reviews, comprehensive listings serve no useful purpose and utilize valuable space. As a general guide, original articles

should have no more than 20 references; case reports, 8 references; and "how to do it" articles, 5 references.

Title Page

- ☐ Give the paper as short a title as possible. Also submit a short title of 3 or 4 words to be used as a running head. Include only the names of the authors directly affiliated with the work, stating for each the single highest academic degree. Include the name and location of no more than two institutional affiliations.
- ☐ If the paper has been or is to be presented at the annual meeting of The Society of Thoracic Surgeons, the Southern Thoracic Surgical Association, or another scientific organization, provide a footnote giving the name, location, and dates of the meeting.
- ☐ At the bottom of the page, type "Address reprint requests to Dr . . ." followed by the last name, exact postal address with zip code, *telephone number*, and *FAX number* of the author to whom communications, proofs, and requests for reprints should be sent.

Abstracts

- ☐ Provide an abstract *no longer than 175 words* for an original article. Abstracts for case reports and "how to do it" articles should be shorter (50 to 75 words). An abstract must accompany *every* contribution, except for letters to the editor. Include several (3 to 5) keywords to assist in cross-indexing the article.

Text

- ☐ Generally, the text should be organized as follows: Introduction, Material and Methods, Results, and Comment.
- ☐ *Cite references, illustrations, and tables in numerical order* in the text. (Order of mention in text determines the number given to each.)
- ☐ Spell out, or define in parentheses, all abbreviations, even if they are commonly employed.
- ☐ Give all measurements and weights in *Système International (SI) units*. See "SI Unit Implementation—the Next Step" (JAMA 1988;260:73–6).
- ☐ For statistical nomenclature and data analysis, follow the "Guidelines for Data Reporting and Nomenclature" published in *The Annals of Thoracic Surgery* (1988;46:260–1) and found in the program book for the annual meeting of The Society of Thoracic Surgeons.
- ☐ Type footnotes at the bottom of the manuscript page on which they are cited. Credit suppliers of drugs, equipment, and other material described at length in the paper in footnotes, giving company name and location.
- ☐ Type acknowledgments, including complete grant or subsidy information, at the end of the text before the references.

References

- ☐ Identify references in the text using arabic numerals in parentheses on the line. Do not cite personal communications, manuscripts in preparation, and other unpublished data in the reference list. They may be mentioned in the text in parentheses.
- ☐ Type references double-spaced on a separate sheet. *Number consecutively in the order in which they are mentioned in the text.*
- ☐ Journal references should provide *inclusive* page numbers; book references should cite *specific* page numbers.
- ☐ Double-check references for accuracy, completeness, and nonduplication.

(Continued)

- ❑ Abbreviations of journals should conform to those used in *Index Medicus*. The style and punctuation of the references should follow the formats outlined below:

Journal Article

8. Grillo HC, Suen HC, Mathisen DJ, Wain JC. Resectional management of thyroid carcinoma invading the airway. *Ann Thorac Surg* 1992;54:3–10.

(List *all* authors if 6 or fewer; otherwise list first 3 and add “et al.”)

Chapter in Book

12. Vouhé PR. Transplantation of thoracic organs in children. In: Fallis JC, Filler RM, Lemoine G, eds. *Pediatric thoracic surgery*. New York: Elsevier, 1991:319–29.

Book (Personal Authors or Editors)

18. Shields TW, ed. *Mediastinal surgery*. Philadelphia: Lea & Febiger, 1991:1–10.

Tables

- ❑ Tables should be typewritten *double-spaced* on separate sheets, each with a table number (arabic) and title above the table and explanatory notes and legends below. Provide a key in alphabetical order to each table to identify all abbreviations used; this key should be placed below any explanatory notes.
- ❑ Include written permission from *both the author and the publisher* to reproduce any previously published table(s).
- ❑ Tables should be self-explanatory, and the data should not be duplicated in the text or illustrations. If a table provides redundant information, it will be deleted.

Legends

- ❑ Type legends double-spaced on a single sheet. Numbers should be arabic and correspond to the order in which the illustrations occur in the text. Identify (in alphabetical order) all abbreviations appearing in the illustrations at the end of each legend. Give the type of stain and magnification power for all photomicrographs.
- ❑ Include written permission from *both the author and the publisher* to reproduce any previously published illustration(s).
- ❑ Enclose signed releases for recognizable (unmasked) photographs of human beings.

Illustrations

- ❑ Submit *triplicate* sets, each set in its own envelope, of *unmounted* and untrimmed black and white professionally prepared glossy prints. Components of the same illustration (eg, parts A and B) should be submitted separately. Photographs, rather than original art or photocopies, should be provided. All lettering should be done professionally and should be of adequate size to retain clarity after reduction (*final* lettering size in print should be 1.5 mm high). Illustrations will be reproduced at a width of one column (8.25 cm, 3¼ inches) or

two columns (17.15 cm, 6¾ inches), or at an intermediate width ranging from 10.16 to 12.07 cm (4 to 4¾ inches).

- ❑ Many computer-generated illustrations are unsatisfactory for reproduction and should be professionally redrawn. Roentgenogram reproductions should be no smaller than 13 × 18 cm (5 × 7 inches).
- ❑ Place the first author's last name, the figure number, and an arrow indicating the *top* on a gummed label on the back of each illustration.
- ❑ If color illustrations are to be considered for publication, submit *both* positive 35-mm transparencies and color prints. Part of the printing costs for color illustrations will be borne by *The Annals*; however, the author must be prepared to pay \$1,150 for the first color illustration on each page and \$250 for every additional color illustration on the same page.

Human Investigation

- ❑ Include the date of approval by the local institutional human research committee or the ethical guidelines that were followed by the investigators in the Material and Methods section of the manuscript.

Humane Animal Care

- ❑ The Material and Methods section must contain a statement assuring that all animals have received humane care in compliance with the “Guide for the Care and Use of Laboratory Animals” published by the National Institutes of Health (NIH Publication No. 85-23, revised 1985).

Conflict of Interest

The Annals expects authors to disclose any commercial association that might pose a conflict of interest in connection with this manuscript. All funding sources supporting the work should be acknowledged in a footnote. Institutional or corporate affiliations of the authors that might constitute a conflict should be brought to the attention of the Editor.

Scientific Responsibility Statement

Before publication of an accepted manuscript, each author will be required to certify that he or she has participated sufficiently in the work to take responsibility for a meaningful share of the content of the manuscript, and that this participation included:

- (a) conception or design of the experiment(s), or collection and analysis or interpretation of data;
- (b) drafting the manuscript or revising its intellectual content; and
- (c) approval of the final version of the manuscript to be published.

Exclusive Publication Statement

I certify that none of the material in this manuscript has been published previously, and that none of this material is currently under consideration for publication elsewhere. This includes symposia, transactions, books, articles published by invitation, and preliminary publications of any kind except an abstract of 400 words or fewer.

(Author's Signature)

Guidelines for the Submission of Electronic Manuscripts

- ☐ Please note that only the final accepted revision of a manuscript should be submitted as an electronic file. If you are planning to submit a manuscript in this format, please check box.

I. Keyboarding of Manuscripts

- 1) Our equipment can handle the following programs (any version) in their "native" format:

IBM Compatible

DisplayWrite	Q & A Write
Executive Writer	Samna
Leading Edge	Spellbinder
MicroSoft Word	Volkswriter
Multimate	WordPerfect
Office Writer	WordStar
PC Write	WordStar 2000
PFS: Write	Xywrite
PFS: Professional	

Macintosh (do not use "Fast Save")

MacWrite
Microsoft Word
WordPerfect

Other word processors should be saved as ASCII files. For files saved as ASCII, consult the editorial office regarding the keyboarding of attributes such as bold, underline, superscript, subscript, etc.

- 2) All design considerations for typefaces, page layout, and artwork will be handled by the publisher after receipt of the electronic manuscript. **There is no need for the author to input special typesetting codes.**
- 3) Be especially sure to distinguish between the letters O and I and the numbers 0 and 1, respectively.
- 4) A "hard return" results from tapping the keyboard's Enter key. Use a hard return only to end a paragraph, or for titles, subheads, separate items on a list, etc. Rely on the word processor's word wrap ("soft return") within paragraphs, list items, etc.
- 5) Use your word processor's capabilities for the following text attributes:
- a) bold
 - b) underline and italic
 - c) subscript
 - d) superscript
 - e) strikeouts

Text that will be italic in published form may be keyboarded italic or underlined.

- 6) Do not use your word processor's hyphenation capabilities. Do not right justify text. Use two hyphens for long dashes.

- 7) In tables, use only tabs, not spaces, to align columns.

II. Organization and Delivery of Electronic Files

- 1) Accepted manuscripts may be submitted on 3.5" or 5.25" diskettes, which must be either MS-DOS or Macintosh format. The author should retain copies of all files as backup. All diskettes must be accompanied by the *final* revision and a duplicate copy of the manuscript (including two clearly separated and labeled sets of illustrations) in full conformity with the standard Information for Authors on the preceding pages.

- 2) Diskettes should each be labeled with:

- a) author's name
- b) short title of article
- c) operating system
- d) format
- e) word processor used, including version number.

For example, DOS/DSDD/WordPerfect 4.2, or MAC/800K/MS Word v.3. Here, *DOS* and *Mac* indicate the operating system, *DSDD* (double-sided, double density) or *800K* indicates the diskette's physical format, and the remainder indicates the word processor used. Labels for your use are available from the Editorial Office.

- 3) If possible, it is helpful to have additional material such as tables, figure legends, and references saved as individual files—one file for each category. A file key should accompany the diskette.

- 4) Submit only the final accepted version of a manuscript. It is essential that submitted electronic files exactly match the final printout.

- 5) Diskettes should be packed between cardboard (or with foam or bubble-wrap) in an envelope that states that magnetic media is contained.

Please submit your word-processing diskette, the final revision and a duplicate copy of your manuscript, and two clearly separated and labeled sets of illustrations to:

Is Coronary Reoperation Without the Pump an Advantage?

Delos M. Cosgrove III, MD

Department of Thoracic and Cardiovascular Surgery, The Cleveland Clinic Foundation, Cleveland, Ohio

Coronary artery reoperation is a mushrooming problem. By 1955 it is estimated that 55,000 patients will undergo coronary reoperations annually in the United States. Reoperative procedures have several technical obstacles that differentiate them from primary procedures. These problems include (1) difficulties with reentry, (2) potential for cardiac and conduit injury during dissection, (3) availability of conduit, (4) management of patent vein grafts, (5) myocardial protection, and (6) bleeding and blood use. In this issue of *The Annals*, Fanning and associates [1] present an alternative approach to reoperative coronary revascularization that eliminates the use of cardiopulmonary bypass. To evaluate the efficacy of this approach, it is necessary to analyze the advantages and disadvantages of this technique and how they relate to the specific problems associated with reoperative myocardial revascularization.

See also page 486.

This technique does not address, eliminate, or reduce the first four of these technical problems. Myocardial protection is simplified but not necessarily improved by elimination of aortic occlusion. Reoperation without the use of cardiopulmonary bypass has a potential advantage for reduction in bleeding secondary to the avoidance of the damaging hematologic influence of cardiopulmonary bypass. With significant improvements in the present-day cardiopulmonary bypass circuit, there are less damaging hematologic effects and it is now less of a problem than previously. New techniques such as intraoperative blood salvage and reinfusion of shed mediastinal blood have reduced the need for homologous blood. In our most recent series of patients undergoing reoperative myocardial revascularization using cardiopulmonary bypass at The Cleveland Clinic, the mean transfusion requirement was 2 units [2].

Electing not to use cardiopulmonary bypass and performing limited procedures that do not replace all grafts increases the potential for two recognized problems. First, manipulation of the heart without interrupting previously placed vein grafts increases the potential for embolization of atherosclerotic debris from old vein grafts. Angiography underestimates the extent and magnitude of the

atherosclerotic process in old vein grafts, making the potential for this complication unpredictable. This complication was noted in Fanning and associates' series, directly causing one of the deaths. Leaving old, patent, and not obviously stenotic vein grafts in place not only exposes the patient to the risk of embolization from under-diagnosed atherosclerotic disease but runs the risk of having the grafts become stenotic in the early postoperative period. This problem was also noted in Fanning and associates series, leading to reoperation.

The avoidance of cardiopulmonary bypass has not proved to reduce the overall mortality. In this series of 54 highly selected patients, the operative mortality rate was 3.4%. In 1,500 consecutive patients operated on at The Cleveland Clinic from 1967 to 1984, the operative mortality was 3.4% [2].

It is clear this procedure is not universally applicable. Fanning and associates recommend its use only for patients who have isolated circumflex disease or for patients with isolated right main or left anterior descending disease or a combination of the two. It is not applicable to patients who require grafting of the posterior descending branch of the right coronary artery or in patients who have vessels less than 2 mm in diameter. This substantially restricts the applicability of this approach to a relatively small percentage of the reoperative population. Fanning and associates employed this technique in 59 of 599 (10%) of their patients.

In summary, avoiding cardiopulmonary bypass may decrease the potential for bleeding and blood requirements in a selected group of patients but fails to substantially improve operative mortality or provide solutions to technical problems related to reoperative coronary artery bypass grafting. It exposes the patients to the risk of thromboembolic events from atherosclerotic vein grafts and early restenosis of untreated vein grafts. Reduction in bleeding complications is an attractive advantage, but the early and long-term risks associated with this approach do not weigh in favor of its widespread implementation.

Warm Blood Cardioplegia: Back to Square One

Benson B. Roe, MD

University of California, San Francisco, California

It appears that the latest fashion on the block is warm blood cardioplegia. That modality of intraoperative myocardial protection is being reported by several surgeons, and clinical acceptance appears to be growing [1–3]. Perhaps it will become the method of choice.

From my viewpoint, however, there remains a skeptical reminder that the history of “new” concepts is often a reincarnation of something old, forgotten, and discarded. Sometimes, of course, a rerun turns out to be surprisingly valuable because someone recognizes or stumbles upon the reason that a seemingly good concept failed and corrects the defect to achieve success. Such was the case with potassium cardioplegia introduced by Dennis Melrose in the late 1950s [4, 5]. His important contribution was initially heralded as a technical bonanza, only to be soon abandoned because of myocardial damage resulting from the high potassium concentration of his solution. It took cardiac surgeons more than a decade to recognize and accept the virtues of potassium cardioplegia at safe lower concentrations. This method of myocardial protection was combined with cardiac cooling and resulted in dramatic reduction of cardiac surgical mortality [6].

Seldom has a new and seemingly heretical modality become so rapidly and universally adopted. Within 2 years of its introduction more than 160 papers on the subject appeared in the English-speaking literature, *none* of which were derogatory or critical of the method and all of which offered some adjunct or reformulation to improve the already gratifying results.

Despite the evidence of effective protection from serious myocardial damage after long periods of aortic cross-clamping there was understandable discomfort about the method's imposition of prolonged ischemia; thus it was not long before oxygenated blood cardioplegia was promoted as an “improvement” on asanguineous crystalloid infusion [7]. More recently this reversionary measure has been augmented by also eliminating hypothermic protection and returning to normal temperatures of the infusate. In light of the history of cardioplegia, one is forced to wonder whether this is an improvement or a step backwards.

The literature is replete with a wide variety of approaches to protect the ischemic myocardium. There are multiple formulas for the infusate—both with and without blood, various patterns of intermittent or constant perfusion, and alternate directions of flow (antegrade or retrograde) [8]. Each proponent provides experience and data to suggest superior performance of one method over another. It is notable, however, that these comparisons,

occasionally of mathematical significance in single parameters, are largely trivial in contrast to the dramatic reduction in operative mortality that accompanied the introduction of simple asanguineous hypothermic potassium cardioplegia. The possible major exception to that statement relates to those patients with acute myocardial infarction [9].

Reversions to abandoned practices may be motivated by dissatisfaction with current methods or may merely be the product of “new” exploration by an “explorer” who is innocent of the reasons why that practice was dropped. The concept of keeping the heart perfused—and nonischemic—under near-normal conditions is appealing and could turn out to be a net benefit. However, it is important to remember that before the era of hypothermic (ischemic) cardioplegia the universally accepted method of myocardial protection was antegrade coronary perfusion with blood from the pump-oxygenator. This logical modality was nevertheless abandoned with alacrity because of its small but distressing incidence of universally fatal “stone heart.”

Three questions arise from this sequence of events: (1) Does myocardial perfusion with warm blood supplemented by cardioplegic solution—whether constant or intermittent—carry the same risks as similar perfusion with just warm blood from the pump-oxygenator without arresting cardiac function? Does “stone heart” continue to be a threat, or is it effectively prevented by the potassium relaxation? (2) Does the growing popularity of this normothermic modality arise from unsatisfactory protection with hypothermic cardioplegia? And, if so, is that dissatisfaction the result of a correctable technical inadequacy? (3) Does hypothermia really have sufficient detrimental effect to justify abandoning its safety and convenience benefits?

The implied or expressed rationale for the “warm” approach is a contention that hypothermia is detrimental to myocardial function, but I am unable to identify evidence of any significant harmful effect either in my clinical experience or the literature. It would seem, therefore, that there is no sound rationale for warm cardioplegia—even if it can be conducted with as much safety as hypothermic cardioplegia.

Buckberg [10], who has been the most voluble proponent of blood cardioplegia, presents evidence that the role of hypothermia in protecting the ischemic myocardium is less important than generally thought, and he elaborates at length on the metabolic factors that are potentially more important. He denigrates the time, expense, and effort associated with cooling the heart but *does not* demonstrate that it is harmful.

Modest concentrations of potassium render the myo-

Address reprint requests to Dr Roe, M-593 University of California, San Francisco, CA 94143-0118.

cardium inactive, and their protective effect is supplemented by hypothermia to an extent that permits long periods of ischemia with demonstrated safety. Imperfections in performance of that technique may be attributable to potassium wash-out by the collateral circulation or to rewarming by both collateral circulation and ambient heat sources. I have noted that these factors are frequently overlooked, which is a possible explanation for suboptimal results. It does, however, hardly make sense to abandon a safe and effective modality only because it is not being used properly.

The temperature gradient between the cold heart and both the surgical ambience and adjacent tissues (particularly the thoracic aorta) can be significantly reduced with (1) the adjunctive use of total body hypothermia, (2) elimination of the heat from overhead operating lights and use of fiberoptic headlights, and (3) covering of the exposed surface of the heart with cold pads or an insulating jacket. Body hypothermia has the supplemental benefit of permitting the pump to be slowed, which lowers pressure, reduces collateral flow, and diminishes oxygenator trauma to the blood. In addition it provides the handy option of stopping the pump (arresting the circulation) with great safety in the event of a power failure, mechanical problem, or just a technical desirability for a bloodless operative field. Although not a common occurrence, there have been several unanticipated episodes in which I have been gratified to use circulatory arrest with safety and comfort.

That safety feature, of course, is dependent on complete and uniform cardiac hypothermia, which can be achieved only with sufficient heat transfer to a volume of cardioplegic solution that is adequate to cool that particular myocardial mass to the desired temperature. A cardioplegic flush with 200 to 300 mL of a refrigerated solution—particularly if it has been standing for some time at room temperature—will effectively paralyze mus-

cular activity but will not provide complete uniform cooling of a 400-g adult heart. Heat exchange objectives should be calculated and a sufficient volume of perfusate should be provided to achieve the cooling objective.

Hypothermia has been a useful modality since the beginnings of open heart surgery. It has served cardiac surgeons and their patients long and well. Let us not be too hasty about abandoning it.

Making Some sENSE Out of Thoracoscopy

Robert B. Wagner, MD

Department of Surgery, Prince Georges Hospital Center, Cheverly, Maryland

Editor's Note:

The following represents a departure in form from the usual editorial comment. In his cover letter, however, Dr Wagner states, "I am fully aware that this manuscript is not in the usual scientific form which you publish in *The Annals of Thoracic Surgery*, but I am very serious about the content."

Another advance in the surgical science,
Has been heralded to us with much reliance,
That through several little holes placed hence and thence,
We may remove all pathology without morbid consequence.

We have applied the procedure with diligence,
To avoid complications with undue frequency,
For not to "keep up" would be impudence,
And forgo any chance of obtaining preeminence.

We use the scope in pleural disease with confidence,
With the lung collapsed it is our preference,
One can abrade, biopsy, and talc dispense,
This procedure really makes a lot of sense.

Lung biopsies and wedges may be done with little violence,
To chest wall muscles lying in residence,
Allowing patients to return to their own home thence,
And quickly to their jobs is the inference.

But to apply it to everything in the chest lacks intelligence,
And forsakes our surgical heritage which we learned as residents,
That good exposure makes for less accidents,
Which is of utmost importance for the patients.

Can one really safely perform resections whence,
Fissures are incomplete and adhesions dense?
It will be a while until there is any evidence,
That keyhole surgery won't lead to more local recurrence.

For fluid intrapericardial lying in residence,
Thoroscopic removal has been touted with grandiloquence.
Can we ignore the simplicity and excellence,
Of the subxyphoid route with benefits immense?

Should local thymic enucleations commence?
Does wide excision really make no difference,
Or are we not reverting to spreading incense,
And forgetting lessons learned from experience?

Esophageal surgery is unforgiving and of great consequence,
Of mistakes made even with exposure of wide circumference,
Should surgery, like Everest—"Because it is there" be condensed,
Or should overextensions of keyholes be considered as negligence?

There is no question of the video's magnificence,
And like TV, it can be sold to a wide audience,
If properly applied it can even cut down on expense,
But it shouldn't be done for the recompense.

Valvular Disease in the Elderly: Influence on Surgical Results

Elizabeth A. Davis, MD, Timothy J. Gardner, MD, A. Marc Gillinov, MD, William A. Baumgartner, MD, Duke E. Cameron, MD, Vincent L. Gott, MD, R. Scott Stuart, MD, Levi Watkins, Jr, MD, and Bruce A. Reitz, MD

Department of Cardiac Surgery, The Johns Hopkins Medical Institutions, Baltimore, Maryland

Aortic valve disease in the elderly is primarily calcific stenosis with preservation of left ventricular function. In contrast, mitral valve disease in the elderly often is ischemic in nature with damage occurring to both valve and myocardium. The present study was undertaken to compare results of aortic (AVR) and mitral valve replacement (MVR) in the elderly and to ascertain predictors of poor outcome. Because patients who had concomitant coronary artery bypass grafting (CABG) are included (51% for AVR, 55% for MVR), patients who had isolated CABG were used as a comparison group. Between January 1, 1984, and June 30, 1991, 1,386 patients aged 70 years and older underwent CABG ($n = 1,043$), AVR ($n = 245$), or MVR ($n = 98$). The operative mortality rates were 5.3% for AVR, 20.4% for MVR, and 5.8% for CABG. Late follow-up of patients undergoing operation in 1984 and 1985 was available for 98% (231/237). Overall survival was comparable for all three groups through the first 5 years of follow-up (AVR, $68\% \pm 8\%$; MVR, $73\% \pm 8\%$; CABG, $78\% \pm 3\%$). After 5 years, survival for patients having AVR and MVR was less than that for those having CABG. Patient age, sex, New York Heart Association functional class, concomitant CABG, prosthetic

valve type, native valve pathology, and preoperative catheterization data were examined as possible predictors of outcome by multivariate logistic regression. Among MVR patients, New York Heart Association functional class, ischemic valvular pathology, and higher pulmonary capillary wedge pressure were predictive of operative mortality; poor left ventricular function was a predictor of poor long-term survival (17% versus 100% at 7 years; $p < 0.0005$). Among AVR patients, only advanced functional class was associated with a poor outcome. Compared with MVR patients, AVR patients were older (76.5 ± 4.6 versus 74.5 ± 3 years; $p = 0.0002$), were more often male (55% versus 39%; $p = 0.006$), had a lower pulmonary capillary wedge pressure (18 ± 11 versus 24 ± 10 mm Hg; $p = 0.0001$), and had fewer critically diseased vessels ($p = 0.001$). These results suggest that AVR in the elderly has an operative mortality similar to that of isolated CABG. In contrast, MVR is less well tolerated, especially in patients with ischemic mitral disease. Survival 5 years postoperatively is similar among AVR, MVR, and CABG patients but becomes significantly worse thereafter for AVR and MVR patients.

(*Ann Thorac Surg* 1993;55:333-8)

One of the most important recent developments in cardiac surgery over the past decade has been the marked increase in the number of elderly patients referred for open heart procedures. At our institution, we have witnessed an increase in mean age of patients undergoing isolated coronary artery bypass grafting (CABG) from 59.7 years in 1984 to 64.2 years in 1990.

Many elderly patients have cardiac valvular lesions that necessitate valve replacement. Aortic valve disease in the elderly is primarily calcific stenosis with preservation of left ventricular function (LVF). In contrast, mitral valve lesions in the elderly are often complex ischemic lesions. Persistent or repeated episodes of ischemia often result in chronic myocardial damage and dysfunction.

This report presents the experience at our institution with valvular operations in elderly patients. By examining mortality rates and risk factors predictive of a poor outcome for aortic (AVR) or mitral valve replacement (MVR), we have attempted to describe the influence of valvular disease on surgical outcome in the elderly.

Material and Methods

This study reviews the data for patients aged 70 years or older who underwent AVR or MVR between January 1, 1984, and June 30, 1991, at The Johns Hopkins Hospital. Because patients who had concomitant CABG are included, elderly patients who had isolated CABG were used as a comparison group. Patients who had multiple-valve replacements are excluded from this report.

Operative Technique

The surgical approach was through a median sternotomy. Extracorporeal perfusion was employed using bubble (earlier years of study) or membrane oxygenators with moderate systemic hypothermia (core temperature, 28° to

Presented at the Twenty-eighth Annual Meeting of The Society of Thoracic Surgeons, Orlando, FL, Feb 3-5, 1992.

30°C). The method of myocardial protection was single-dose cold (4°C) crystalloid hyperkalemic cardioplegia injected into the aortic root after placement of the aortic cross-clamp and continuous topical cooling with cold saline solution. Perfusion flow rates were maintained between 1.8 and $2.8 \text{ L} \cdot \text{min}^{-1} \cdot \text{m}^{-2}$ with mean arterial pressure between 50 and 70 mm Hg. A pulmonary artery vent was routinely employed.

Data Acquisition

Data were obtained by retrospective review of medical records, catheterization and pathology reports, death certificates, and autopsy reports. Data collected from medical records included New York Heart Association (NYHA) functional class, surgical status (elective versus urgent/emergent), and number of postoperative hospital days. Catheterization data consisted of LVEF, pulmonary capillary wedge pressure, number of critically diseased vessels ($\geq 70\%$ narrowing of the luminal diameter), trans-valvular gradient, valve area, and degree of regurgitation (graded angiographically from 1 to 4+). Operative reports provided the surgical procedure, valve prosthesis, and gross valvular pathology. Additional description of valvular pathology was obtained from formal pathology reports. Death certificates and autopsy reports provided dates and causes of death.

Follow-up Data

Follow-up information was obtained on patients who underwent operation in 1984 and 1985. Telephone contact was made with the patient, a family member, or the patient's current physician.

Statistical Analysis

Univariate analysis of potential risk factors for early mortality was performed using χ^2 analysis for discrete variables and unpaired t tests and analysis of variance for continuous variables. To determine independent predictors of mortality, variables with a p value of less than 0.1 in the univariate analysis were entered as covariates in a multivariate logistic regression model that contained age and sex (SAS Institute Inc, Cary, NC).

Factors possibly predictive of long-term survival were examined individually by Kaplan-Meier actuarial analysis, and their significance was determined by the Breslow test (BMDP Statistical Software, Los Angeles, CA).

All values are expressed as the mean $\pm$ one standard deviation except survival data, for which the standard error is reported. A p value of less than 0.05 was considered significant.

Results

The study population consisted of 1,386 patients: 245 underwent AVR, 98 underwent MVR, and 1,043 had isolated CABG. One hundred twenty-five (51%) of the patients who had AVR and 54 (55%) of the patients who had MVR had concomitant CABG. There were 135 men (55%) and 110 women (45%) in the AVR group, 38 men (39%) and 60 women (61%) in the MVR group, and 665 men (64%) and 378 women (36%) in the CABG group.

Table 1. Summary of Patient Data^a

3-Vessel disease	39 (16)	35 (36)

^a Numbers in parentheses are percentages. ^b Data are for patients with pure aortic stenosis only.

AVR = aortic valve replacement; LVEF = left ventricular function; MVR = mitral valve replacement; NYHA = New York Heart Association; PCWP = pulmonary capillary wedge pressure.

Clinical, hemodynamic, and angiographic characteristics of patients having valve replacement are summarized in Table 1. Bioprostheses were used in 193 AVRs (79%) and 66 MVRs (67%). Five (three AVRs, two MVRs) were Ionescu-Shiley bovine valves; all others were Carpentier-Edwards porcine valves. All mechanical prostheses were St. Jude Medical valves except for one Medtronic valve in the AVR group.

Native valve pathology is detailed in Table 2. Pure aortic stenosis accounted for 208 (85%) of all aortic valve

Table 2. Valvular Pathology^a

Variable	Aortic (n = 245)	Mitral (n = 98)
Pure stenosis	208 (85)	16 (16)
Pure regurgitation	19 (8)	61 (62)
Mixed stenosis and regurgitation	18 (7)	21 (22)
Calcific	210 (86)	4 (4)

Endocarditis	7 (3)	5 (5)
Other	17 (7)	7 (7)

^a Numbers in parentheses are percentages.

Fig 1. Incidence of two- and three-vessel disease according to valvular pathology. (AVR = aortic valve replacement; MVR = mitral valve replacement.)

lesions. One hundred ninety-nine (96%) of these 208 lesions were calcific in nature. Pure mitral regurgitation occurred in 61 patients (62%). Among all patients having MVR, rheumatic disease was suspected in 35 patients (36%). Ischemic lesions were the second most prevalent lesion, occurring in 30 patients (31%).

Figure 1 shows the incidence of severe two- and three-vessel coronary artery disease (CAD) in AVR and MVR patients according to valvular pathology. Only 29% (71/245) of AVR patients and no more than 50% of any pathological subgroup had disease of two vessels or more. In contrast, 46% (45/98) of MVR patients had severe CAD. The incidence was highest in patients with ischemic pathology (90%; 27/30).

The median number of days spent in the hospital postoperatively was 11 for AVR and 14 for MVR.

The 30-day mortality rate was 3.3% (8/245) for AVR and 14.3% (14/98) for MVR. In comparison, similarly aged patients undergoing CABG had a mortality rate of 4.7% (49/1,043). The in-hospital mortality rate was 5.3% (13/245) and 20.4% (20/98) for AVR and MVR, respectively. Elderly CABG patients had a hospital mortality rate of 5.8% (61/1,043) (Table 3). In-hospital mortality rates for valve

Table 3. Thirty-Day and In-Hospital Mortality Rates^a

Mortality	AVR (n = 245)	MVR (n = 98)	CABG (n = 1,043)
30-Day	3.3% (1%-5.5%)	14.3% (7.2%-21.3%)	4.7% (3.4%-6%)
In-hospital	5.3% (2.5%-8.1%)	20.4% (12.3%-28.5%)	5.8% (4.3%-7.2%)

^a Numbers in parentheses show 95% confidence interval.

AVR = aortic valve replacement; CABG = coronary artery bypass grafting; MVR = mitral valve replacement.

Fig 2. Actuarial survival for elderly patients undergoing aortic valve replacement (AVR), mitral valve replacement (MVR), and coronary artery bypass grafting (CABG).

replacement alone were 3.3% (4/120) for AVR and 11.4% (5/44) for MVR. Concomitant CABG increased these rates to 7.2% (9/125) for AVR and 27.8% (15/54) for MVR.

In the MVR group, 70% (14/20) of the deaths occurred in patients who were seen with ischemic valvular disease. Operation was urgently or emergently performed in 69% (9/13) of the AVR patients and 85% (17/20) of the MVR patients who died. The percentage of in-hospital deaths from cardiac-related causes was 40% (8/20) for MVR and 41% (25/61) for CABG but only 31% (4/13) for AVR. Among those patients who died in-hospital but beyond the immediate 30-day postoperative period, cardiac-related deaths were infrequent and occurred in only 2 MVR patients and no AVR or CABG patients.

Information on late mortality for patients seen in the first 2 years of the study was available on 231 (98%) of 237 patients. In particular, follow-up data were obtained on 100% (54/54) of the patients having a valve procedure. The mean duration of follow-up was 78.6 ± 7 months. Survival rates for AVR, MVR, and CABG are shown in Figure 2. Survival was similar among the three groups through 5 years of follow-up: AVR, $68\% \pm 8\%$; MVR, $73\% \pm 8\%$; and CABG, $78\% \pm 3\%$. After this, the AVR and MVR patients did significantly worse ($p < 0.05$) with 7-year survival rates of $61\% \pm 8\%$ for AVR and $63\% \pm 8\%$ for MVR compared with $75\% \pm 3\%$ for CABG.

A number of factors were analyzed as possible predictors of surgical outcome:

- Age
- Sex
- NYHA functional class
- Valvular lesion
- Stenotic
- Regurgitant

- Stenotic and regurgitant
- Left ventricular function
- Pulmonary capillary wedge pressure
- Number of critically diseased vessels
- Concomitant coronary artery bypass grafting
- Number of coronary grafts
- Type of prosthesis
 - Bioprosthetic
 - Mechanical
- Valvular pathology
 - Calcific
 - Rheumatic
 - Ischemic
 - Degenerative
 - Endocarditis

For MVR, NYHA functional class ($p = 0.03$), pulmonary capillary wedge pressure of 25 mm Hg or more ($p = 0.049$), and ischemic valvular pathology ($p = 0.01$) were significant predictors of early mortality. For AVR, only NYHA functional class was a significant correlate ($p = 0.02$). Compared with MVR patients, AVR patients were older ($p = 0.0002$), were more often male ($p = 0.006$), had a lower pulmonary capillary wedge pressure ($p = 0.0001$), and had fewer critically stenosed vessels ($p = 0.001$). By univariate analysis, neither aortic valve gradient nor aortic valve area was a significant predictor of early mortality for patients with pure aortic stenosis. Similarly, the degree of aortic or mitral regurgitation did not predict death in patients with purely regurgitant lesions. Only poor LVF was predictive of late death for MVR patients (17% versus 100% survival at 7 years; $p < 0.0005$).

Comment

Cardiac operations are being performed in elderly patients with increasing frequency and encouraging results. For example, AVR in the elderly has an operative mortality rate of 5% to 10% [1-12] with long-term survival rates similar to that of age- and sex-matched patients in the general population [8, 11]. These results have been attributed to improvements in patient selection, myocardial protection, and postoperative care.

However, the septuagenarian or octogenarian is not simply the aged equivalent of the younger patient. In the elderly patient, there is a higher incidence of coexisting and serious morbidity, which adversely affects operative outcome [10, 11, 13]. It is noteworthy that most cardiac-related deaths in this series occurred within 30 days of operation. Deaths occurring after that time but in-hospital were usually due to failure of multiple organ systems, demonstrating the precarious physiologic homeostasis present in elderly patients.

Furthermore, the elderly heart is affected by a different spectrum of diseases. With age, the aortic valve undergoes fibrosis and calcification such that senile aortic stenosis is one of the most prevalent valvular lesions in the elderly. In the present study, calcific aortic stenosis was the indication for AVR in 85% (209/245).

With advanced age also come an increased incidence of

CAD and the effect of ischemia on the myocardium and valvular function. Ischemic mitral regurgitation constitutes a sizable proportion of mitral lesions seen in the elderly. In this series, 30 MVR patients (31%) had ischemic pathology. However, this classification underestimates the true incidence of ischemic heart disease in patients undergoing MVR. As shown in Table 1, 64 (65%) of MVR patients had at least one diseased coronary artery, and 45 (46%) had severe two- or three-vessel disease. Thus, nonischemic valvular pathology did not preclude the presence of serious CAD. Nevertheless, ischemic mitral valve disease identified a subset of patients with severe CAD. The incidence of two- and three-vessel disease in these patients was 90% (27/30).

Pure calcific aortic stenosis typically causes concentric hypertrophy of the left ventricle, which may regress after relief of the outflow obstruction. In all but the end-stage case, there is usually little permanent damage to the myocardium, and patients fare well postoperatively [14]. Indeed, in our series, the early mortality rate of 5.3% for patients undergoing AVR was essentially the same as that of patients having isolated CABG (5.8%), comparable with [6, 8] or less than [3, 11] results reported in other series. Concomitant CABG increased the mortality rate from 3.3% (AVR alone) to 7.2% (AVR + CABG). This finding was also noted in other reports [1, 3, 5, 9, 10] and raises the question how aggressively revascularization should be pursued in the elderly patient with aortic valve disease, especially in the patient without demonstrable preoperative ischemia. The additional intraoperative ischemic time required for bypass grafting may not have been well tolerated. On the other hand, more advanced ventricular dysfunction in patients requiring concomitant CABG may have contributed to the increased mortality rate. Because most patients in this series with coronary lesions amenable to revascularization underwent bypass grafting, the outcome of isolated valve replacement in such patients is not known. Clearly, further studies addressing these issues are needed.

Only NYHA functional class correlated with early mortality for AVR. In particular, poor LVF did not correlate with mortality. These results are in agreement with those of Levinson and colleagues [4] in their report of AVR in octogenarians with aortic stenosis. This finding is also consistent with what is known of the natural history of aortic stenosis. Left ventricular function is well preserved until late in the course of the disease. Even then, valve replacement is sometimes curative, and ventricular function is restored to normal [14].

Long-term survival for the first 5 years after AVR paralleled that of CABG patients. The decline in relative survival thereafter is difficult to explain, as no risk factors were identified. Older age in AVR patients compared with MVR or CABG patients may have been contributory.

In contrast to calcific disease, ischemic disease may damage not only the valve but also the myocardium. In this situation, valve replacement may do little to improve left ventricular dysfunction, and the condition of patients may continue to deteriorate [15]. Seventy percent of in-hospital deaths after MVR occurred in patients with

ischemic mitral valve disease. The overall early mortality rate of 20.4% for MVR patients was substantially higher than that of the AVR or CABG group.

Multivariate analysis demonstrated that factors indicative of ischemic disease (higher pulmonary capillary wedge pressure and ischemic pathology) were the most important predictors of early death. Tsai and co-workers [9] also found that patients with acute ischemic syndromes require longer periods of cardiopulmonary bypass and cross-clamp time and have increased mortality.

Although the number of critically diseased vessels was not found to be a correlate of early death, MVR patients had substantially more CAD than AVR patients. Furthermore, MVR patients who required concomitant coronary revascularization had a substantially higher mortality rate than those who did not (27.8% versus 11.4%), possibly reflecting a greater degree of ischemic myocardial damage. This finding raises the same issues of routine revascularization in elderly patients undergoing valve replacement.

Although only 11% of MVR patients had poor LVF, this is probably an underestimation, especially given that 31% of the patients had ischemic disease and 98% were in NYHA class III or IV. Typically, LVF is determined by calculating ejection fraction from planimeter areas of left ventricular images in right anterior oblique and left anterior oblique projections. Conditions such as ischemic mitral regurgitation that decrease afterload may cause a misleading normalization of the ejection fraction despite real deterioration in function. Thus, it is likely that many more MVR patients had poorly functioning ventricles than is implied by the catheterization results.

It is interesting that poor LVF did not emerge as a significant predictor of early mortality but did correlate with poor long-term survival. It may be that valve replacement (with or without revascularization) in these patients is temporizing but not curative. Although cardiac performance is stabilized or even improved in the immediate postoperative period, LVF may continue to deteriorate further.

The published literature contains many reports on the outcome of valve operations in elderly patients. The majority of these have been written (1) to justify an aggressive surgical approach when medical therapy has failed, (2) to refute aortic valvuloplasty as a viable alternative to surgical intervention, or (3) to demonstrate acceptable mortality rates. Our study is unusual in that it examines how valvular disease in the elderly affects surgical outcome. Our results suggest that outcome after valve replacement in elderly patients is primarily a function of the damage incurred by the myocardium as a result of the primary disease, particularly the severity and extent

of CAD. Thus, most elderly patients who undergo AVR are seen with a calcified stenotic aortic valve but a well-functioning ventricle. The degree of CAD is markedly less than that in MVR patients. Operative outcome is excellent for AVR, with an early mortality similar to that of isolated CABG. In contrast, patients requiring MVR have more serious ischemic disease, which damages both valve and myocardium. Operative outcome is worse in these patients, and long-term survival is dependent primarily on LVF.

DISCUSSION

DR CARY W. AKINS (Boston, MA): In the series you presented, were there any patients who had mitral valve reconstruction rather than mitral valve replacement? Has the team at Johns

Hopkins looked at results in that group to find out whether the results in patients who have damaged left ventricles are better if the valve can be repaired rather than replaced?

DR DAVIS: We did not include patients undergoing mitral valve repair in this study. Seventy percent of the mitral valve replacement patients who died had severe ischemic disease, typically with papillary muscle rupture or dysfunction. For such patients, valve replacement was the procedure of choice. Patients who underwent mitral valve repair had much less severe disease. Thus, a comparison of outcome for repair versus replacement would be more reflective of the patient's preoperative cardiac function than of the surgical procedure.

DR D. CRAIG MILLER (Stanford, CA): How many of the mitral valve replacements for mitral regurgitation were done with preservation of both or one of the leaflets and chordal apparatus?

DR DAVIS: I regret that I do not have the data to answer that question.

DR BRUCE A. REITZ (Baltimore, MD): Increasingly through the years the chordal apparatus was spared. However, I do not think that was specifically looked at in this study, and so I cannot answer that question.

DR MILLER: At least by inference, Dr Davis told us a minute ago that the regurgitant mitral valves really were not reparable unless you were willing to reattach ruptured papillary muscles. Could we have comments from Dr David and Dr Cosgrove about how wise (or unwise) this is in patients older than 70 years, the vast majority of whom had coronary disease?

DR TIRONE E. DAVID (Toronto, Ont, Canada): I do not repair the mitral valve in patients with ischemic mitral insufficiency, particularly when it is acute. However, when the patient has chronic insufficiency and there is also a component of myxomatous degeneration, I do undertake repair, and the results have been good. When the insufficiency is purely on the basis of papillary muscle-ventricular wall dysfunction or due to acute papillary mus-

cle rupture, I replace the mitral valve. My experience with mitral valve repair in these patients has been disappointing.

DR MILLER: You are distinguishing these patients from patients who just need a ring or a posterior ring for dilatation?

DR DAVID: In our experience, the most common cause of mitral regurgitation due to ischemia is limited mobility of the leaflets along the posteromedial commissure and not prolapse of the leaflets. In 90% of cases, the posteromedial papillary muscle and the posterior left ventricular wall do not contract well, and the wall bulges in systole. This abnormal wall motion drags the medial commissure into the ventricle. It is possible to correct the regurgitation by performing an asymmetrical annuloplasty. The fate of this type of repair is unpredictable because the left ventricle may continue to dilate and mitral regurgitation may recur.

DR DELOS M. COSGROVE III (Cleveland, OH): Ischemic mitral valve disease continues to be a very serious problem and one that has carried a high mortality. My associates and I have not been able to demonstrate that mitral valve repair has improved long-term survival. Survival after mitral valve operation for ischemic mitral disease is directly related to the function of the left ventricle. Patients with dilated left ventricles have a very poor prognosis.

DR MILLER: Doctor Davis, could you tell us how you quantified left ventricular systolic function, specifically in patients with mitral regurgitation? You mentioned that it was an adverse predictor of late survival in the patients having mitral valve replacement. You did not study just ejection fraction, I hope.

DR DAVIS: Left ventricular function was determined at catheterization by several variables: wall motion, ejection fraction, and end-diastolic pressure. Patients with poor left ventricular function typically had ejection fractions less than 0.30 and end-diastolic pressures greater than 15 mm Hg.

Damus-Kaye-Stansel With Cavopulmonary Connection for Single Ventricle and Subaortic Obstruction

Charles B. Huddleston, MD, Charles E. Canter, MD, and Thomas L. Spray, MD

Divisions of Cardiothoracic Surgery and Pediatric Cardiology, Washington University School of Medicine, St. Louis Children's Hospital, St. Louis, Missouri

Infants with single ventricle and transposition of the great arteries with or without aortic arch obstruction have a poor prognosis due in large part to the development of systemic outflow obstruction, a frequent consequence of pulmonary artery banding. Thus, the initial palliation and long-term treatment options are critical in terms of surgical choices and timing. We report our experience with 9 patients managed by neonatal pulmonary artery banding and early debanding, a Damus-Kaye-Stansel procedure, and either a modified Glenn shunt or a modified Fontan procedure. Some evidence of subaortic stenosis developed in every patient as manifested by a resting gradient across the systemic outflow tract (21.4 ± 4.2 mm Hg), a small ventricular septal defect relative to the body surface area (1.57 ± 0.39 cm²/m²), and a small ventricular septal defect relative to the aortic root cross-

sectional area (0.70 ± 0.04 cm²/m²). There were 1 early death and 1 late death after the Damus-Kaye-Stansel procedure. With the exception of 1 patient, the in-hospital course of the survivors was relatively uncomplicated. Two patients with levotransposition of the great arteries have required pacemakers. None of the survivors have residual systemic outflow obstruction. There is trivial or mild pulmonic insufficiency in 5 patients, which is not progressing. One patient had mild to moderate pulmonic insufficiency but died late presumably of an arrhythmia. We conclude that neonatal pulmonary artery banding coupled with planned early debanding, a Damus-Kaye-Stansel procedure, and cavopulmonary anastomosis is a relatively low-risk course for patients with this complex physiology.

(*Ann Thorac Surg* 1993;55:339-46)

The prognosis for infants with single ventricle physiology in whom subaortic stenosis either is present or develops is very poor whether or not an attempt at surgical correction is made [1-4]. This obstruction to systemic outflow occurs most frequently in the subset of infants with a dominant left ventricle, transposition of the great arteries (TGA) such that the aorta comes off the rudimentary right ventricle, and unobstructed pulmonary blood flow particularly when there is aortic arch obstruction. Systemic flow exits the heart into the aorta through a ventricular septal defect (VSD), which is usually of a muscular type (Fig 1A). To protect the pulmonary vasculature and to control heart failure, banding of the pulmonary artery (PA) has been the conventional approach along with repair of the aortic arch obstruction when present (Fig 1B). This approach frequently produces major subaortic stenosis and subsequent left ventricular hypertrophy, both adverse preoperative conditions for patients destined for a Fontan type of correction. Fewer than half the patients in whom subaortic stenosis develops after PA banding survive to even be candidates for the Fontan operation [4, 5].

Although all these patients will need a procedure to limit pulmonary blood flow, it has been suggested that PA banding be abandoned because of its tendency to produce subaortic stenosis and that initial palliation should be anastomosis of the unobstructed PA exiting the dominant ventricle to the ascending aorta, repair of the aortic arch (if necessary), and performance of a systemic-pulmonary shunt in early infancy [5-8]. This, too, carries a very high mortality rate of approximately 50% when done in infants less than 3 months of age.

Because of the bleak results of both the conventional and the more radical approaches to this group of patients, we have adopted a policy of PA banding with arch repair in the newborn period followed by early takedown of the PA band coupled with a Damus-Kaye-Stansel (DKS) procedure (proximal PA-ascending aorta anastomosis) and cavopulmonary anastomosis (modified Glenn shunt or Fontan procedure). This report summarizes our results with this approach.

Material and Methods

Patient Population

We reviewed the records of all patients who underwent a DKS procedure with cavopulmonary connection at St. Louis Children's Hospital. There were 9 such patients, 5

Presented at the Twenty-eighth Annual Meeting of The Society of Thoracic Surgeons, Orlando, FL, Feb 3-5, 1992.

Address reprint requests to Dr Huddleston, St. Louis Children's Hospital, Suite 5W24, 400 S Kingshighway, St. Louis, MO 63110.

Fig 1. (A) The typical anatomy for these patients is the aorta coming off a rudimentary right ventricle and the pulmonary artery, off the left ventricle. Systemic outflow reaches the aorta through a muscular ventricular defect (speckled area in the drawing on the left). (B) Pulmonary artery banding is the initial palliative procedure. (C) The Damus-Kaye-Stansel procedure is performed by dividing the pulmonary artery at the band site, anastomosing it end-to-side to the ascending aorta, and oversewing the distal main pulmonary artery. (D) The superior vena cava is then divided and its distal end sewn end-to-side to the right pulmonary artery, thus creating the modified Glenn shunt. (E) The proximal superior vena cava is oversewn if the patient is not a candidate for the modified Fontan correction. (F) For a candidate for the Fontan procedure, an atrial baffle is created to divert the inferior vena cava blood to the superior vena cava, which is then anastomosed end-to-side to the inferior aspect of the right pulmonary artery or to the distal end of the transected main pulmonary artery.

Table 1. Summary of Patient Data

Patient No.	Anatomic Diagnosis	Initial Palliation	Age at PAB (d)	Age at DKS Procedure (mo)	Outcome
1	TA, D-TGA, CoA	PAB, repair of CoA	21	10 ^a	Alive and well
2	SV, CAVC, D-TGA	PAB	14	5 ^a	Alive; Fontan at 35 mo
3	DILV, L-TGA	PAB	48	16 ^a	Alive; developed heart block requiring pacemaker
4	TA, D-TGA, IAA	PAB, repair of IAA	6	12 ^a	Alive; Fontan at 35 mo
5	TA, L-TGA, CoA	PAB, repair of CoA	93	11 ^a	Died late of arrhythmia
6	MV atresia, hypoplastic LV, CoA	PAB, repair of CoA	17	14 ^b	Died postop of CNS event
7	TA, D-TGA	PAB	44	34 ^b	Alive and well
8	TA, L-TGA, situs inversus	PAB	48	37 ^b	Alive; required closure of aortopulmonary fistula
9	DILV, D-TGA, CoA	PAB, repair of CoA	2	15 ^b	Alive; intermittent heart block requiring pacemaker
Mean	...	...	32 ± 5	17 ± 3	...

^a Damus-Kaye-Stansel procedure was performed in combination with a modified Glenn shunt.

^b Damus-Kaye-Stansel procedure was performed in combination with Fontan procedure.

CAVC = complete atrioventricular canal; CNS = central nervous system; CoA = coarctation of aorta; DILV = double-inlet left ventricle; DKS = Damus-Kaye-Stansel; D-TGA = dextrotransposition of the great arteries; IAA = interrupted aortic arch; L-TGA = levotransposition of the great arteries; LV = left ventricle; MV = mitral valve; PAB = pulmonary artery banding; SV = single ventricle; TA = tricuspid atresia.

of whom underwent a modified Glenn shunt at the time of the DKS procedure and 4, a modified Fontan procedure. Their characteristics are summarized in Table 1.

All patients were treated initially with PA banding, and 5 also required repair of aortic arch obstruction (coarctation of the aorta or interrupted aortic arch). The primary cardiac diagnoses in all patients were some variation of single ventricle with TGA and unobstructed pulmonary blood flow. Five patients had tricuspid atresia, 2 had double-inlet left ventricle, and two others had complex single-ventricle variants. The average age at PA banding was just older than 1 month, and the average age at the DKS procedure was 17 months. Those undergoing a DKS operation with a modified Glenn shunt were operated on at an earlier age (average age, 10.8 ± 1.9 months; range, 5 to 16 months) than those undergoing this operation with a modified Fontan procedure (average age, 25.0 ± 3.5 months; range, 14 to 37 months). Their medical records, echocardiograms, and cardiac catheterization results were examined. Follow-up was 100%.

The echocardiograms were reviewed by a single individual (C.E.C.) to assess the size of the VSD, the degree of ventricular hypertrophy, the ventricular chamber dimensions, and the presence of postoperative pulmonic insufficiency (PI). Pulmonic insufficiency was graded according to the size of the regurgitant jet: trivial = barely perceptible with color flow Doppler, mild = a very small jet beneath the semilunar valve, and mild to moderate = slightly greater than barely beneath the valve. The VSD size was measured in a fashion similar to that described by Matitiau and co-workers [9]. Relative size of the VSD was then appraised by relating it to the body surface area of the patient and to the aortic root cross-sectional area. Ventricular hypertrophy was assessed by measuring the

thickness of the posterior and septal walls of the dominant ventricle in diastole. The end-diastolic diameter of the dominant ventricle was measured at the level of the papillary muscles. The ventricular wall thickness and end-diastolic diameter were related to echocardiographically obtained normal values in growing children [10].

Follow-up information was derived from outpatient visits at St. Louis Children's Hospital or by communication with the local physician.

Surgical Procedure

Through a median sternotomy, the patients were placed on standard cardiopulmonary bypass using bicaval cannulation. The superior vena cava was cannulated at its junction with the innominate vein. Systemic cooling was performed to 28°C, and the heart was arrested with hyperkalemic cold crystalloid cardioplegia. The main PA was divided just proximal to the band, and the distal end was oversewn (Fig 1C). An appropriate site on the ascending aorta was selected for the main PA-aorta anastomosis, this usually being on the posterior surface just above the commissures of the aortic valve. A small segment of aorta was excised, and the anastomosis was constructed using monofilament absorbable suture. For those patients undergoing a bidirectional Glenn shunt, the aortic cross-clamp was removed at this point (Figs 1D, 1E). The superior vena cava was divided just above the right atrium, and its proximal end was oversewn. The distal end was then sewn end-to-side to the right PA. For patients undergoing the modified Fontan procedure, closure of the atrial septal defect and atriopulmonary anastomosis were carried out with the cross-clamp applied (Fig 1F).

Table 2. Assessment of Subaortic Obstruction^a

Variable	Initial	Before DKS Procedure
Pressure gradient (mm Hg)	... ^b	21.4 ± 4.2
VSD size (cm ²)	0.61 ± 0.25	0.68 ± 0.27
VSD/BSA ratio (cm ² /m ²)	2.63 ± 0.79	1.57 ± 0.39
VSD/aortic root area ratio	1.03 ± 0.05	0.70 ± 0.04

^a Data are shown as the mean ± the standard error of the mean. ^b Not all patients underwent cardiac catheterization when first seen; data are incomplete.

BSA = body surface area; DKS = Damus-Kaye-Stansel; VSD = ventricular septal defect.

Results

Data are expressed as the mean ± the standard error of the mean.

Degree of Subaortic Stenosis

The degree of subaortic stenosis was evaluated using the resting gradient across the VSD at cardiac catheterization and by assessing the size of the VSD on echocardiography in relation to the body surface area and the cross-sectional area of the aortic root (Table 2). The mean gradient was 21.4 mm Hg (range, 5 to 55 mm Hg). The VSD size at initial evaluation was 0.61 ± 0.25 cm² and increased minimally to 0.68 ± 0.27 cm². This was related to the growth and size of the patient in two ways. The mean VSD to body surface area ratio at initial evaluation (approximately 1 month of age) was 2.63 ± 0.79 cm²/m². This corresponds to the value suggested by Matitau and colleagues [9] to be not predictive of the development of major subaortic stenosis in this setting. However, at follow-up evaluation this value dropped to 1.57 ± 0.39 cm²/m², which is predictive of critical subaortic stenosis. The corresponding values for the ratio of the VSD to aortic root cross-sectional area were 1.03 ± 0.05 initially and 0.70 ± 0.04 at follow-up. Thus, the size of the VSD decreased on a relative basis after PA banding and became significantly obstructive.

Ventricular Dimensions

Measurements of the ventricular dimensions were also performed echocardiographically to assess chamber size and degree of ventricular hypertrophy (Fig 2). These were expressed as percent of normal. The initial echocardiogram was obtained when the patient was about 1 month of age; the next, during the same hospitalization as the DKS procedure; and the follow-up echocardiogram, at a mean of about 4 months after the DKS procedure. The degree of ventricular hypertrophy increased during the time that the PA band was in place and remained essentially unchanged at early follow-up. The end-diastolic diameter increased somewhat as well, but then returned to slightly less than the initial value in the follow-up study.

Hemodynamics Before DKS Procedure

The preoperative assessment of the integrity of the pulmonary vasculature revealed an average mean PA pres-

Fig 2. Changes in ventricular posterior and septal wall thicknesses and ventricular end-diastolic diameter over time as assessed by echocardiography. After pulmonary artery banding (Initial), there is obvious development of ventricular hypertrophy, which persists at early follow-up (mean time, about 4 months). The ventricular end-diastolic diameter, an estimation of ventricular volume, increases until the Damus-Kaye-Stansel (DKS) procedure is performed and then falls back to nearly normal levels.

sure of 19.6 mm Hg and an average pulmonary vascular resistance of 1.9 Wood units with a pulmonary to systemic flow ratio of 1.7:1 and a left ventricular end-diastolic pressure of 7.3 mm Hg (Table 3).

Operative Results

The operative procedures were performed using standard cardiopulmonary bypass in all patients except 1 who required circulatory arrest. The average bypass time was 88.3 minutes, and the average aortic cross-clamp time was 38 minutes (Table 4).

Eight of the 9 patients had excellent hemodynamics when they were taken from the operating room; 1 patient required a high central venous pressure of 20 to 22 mm Hg. This patient had atresia of the left atrioventricular valve and a hypoplastic left ventricle with a dominant right ventricle. His preoperative evaluation revealed relatively high pulmonary vascular resistance.

Table 3. Cardiac Catheterization Data Before Damus-Kaye-Stansel Procedure^a

Variable	Value
Right atrial pressure (mm Hg)	7.6 ± 1.7
Mean PA pressure (mm Hg)	19.6 ± 3.3
Pulmonary vascular resistance (Wood units)	1.9 ± 1.2
Q _p /Q _s	1.7 ± 0.9
LVEDP (mm Hg)	7.3 ± 2.0
SaO ₂ (%)	79.6 ± 2.6

^a Data are shown as the mean ± the standard error of the mean.

LVEDP = left ventricular end-diastolic pressure; PA = pulmonary artery; Q_p = flow to pulmonary vascular bed; Q_s = flow to systemic vascular bed; SaO₂ = systemic arterial oxygen saturation.

Initially he had a modified Blalock-Taussig shunt in conjunction with the DKS procedure but could not be weaned from cardiopulmonary bypass because of poor oxygenation. The shunt was taken down, and his correction was converted to a modified Fontan procedure. The patient then was successfully weaned from cardiopulmonary bypass albeit with somewhat unstable hemodynamics. His condition was improving, but evidence of brain death suddenly developed about 12 hours postoperatively. Postmortem examination showed brain edema only as the cause of death.

There were only 2 patients with early complications. One had mild pleural effusions. In the other, severe chylothorax and respiratory failure complicated by *Candida* sepsis developed. This was caused by a persistent aortopulmonary fistula between the proximal and distal PA after a DKS procedure with a Fontan procedure. Once this fistula was divided, the patient had a completely unremarkable postoperative course.

Follow-up

The average follow-up is 22.2 months for the survivors (Table 5). There was 1 late death. This occurred in a patient with tricuspid atresia, TGA, and coarctation who underwent a DKS procedure with a modified Glenn shunt at 11 months of age. He had a completely unremarkable postoperative course and was discharged after 5 days. He died suddenly at home of a presumed arrhythmia; at postmortem examination, he had a markedly hypertrophied ventricle but no other major findings.

To date, late complications have occurred in 2 patients. Both required a permanent pacemaker for bradyarrhythmias: complete heart block in 1 and second-degree heart block in the other. Both patients have levo-TGA and single ventricle. All the survivors are in class I. Two of the 5 patients treated with a modified Glenn shunt have since undergone completion of the modified Fontan procedure.

Assessment of the DKS anastomosis during follow-up has been done by echocardiography in all 8 operative survivors. At 1 week postoperatively, 6 of the 8 had some degree of PI: trivial or mild in 5 and mild to moderate in 1. At an average of 16 months later, none of these patients has shown progression of PI, and in 2, it has been downgraded from mild to trivial. The 1 patient with mild to moderate PI is the patient who died suddenly presum-

Table 5. Summary of Follow-up Data

Variable	Value
Mean follow-up (mo)	22.2 $\pm$ 3.1
Late deaths	1
Complications

Gradient across DKS	0 (by echo)
Presence of PI by echo (early/late)	
Trivial	1/3
Mild	4/2
Mild to moderate	1/0 ^a

^a The patient with mild to moderate PI early postoperatively died late.

DKS = Damus-Kaye-Stansel; PI = pulmonary insufficiency.

ably of an arrhythmia. None of the patients have any evidence of a gradient across the new outflow tract of the single ventricle.

Comment

Although originally proposed as treatment of TGA [11-14], the DKS procedure has provided greater versatility for the treatment of other, more complex congenital cardiac anomalies [13]. It seems particularly well suited for circumstances in which an otherwise normal pulmonary valve and proximal main PA exit a single ventricle with an aorta and aortic valve exiting a rudimentary ventricle within which there is partial obstruction in the form of a restrictive VSD. If the Fontan procedure is to be performed, this pulmonary valve is a dead end for outflow from the single ventricle if not used in the systemic circulation to relieve the obstruction there.

There are sufficient data at present demonstrating the risk of development of subaortic stenosis in infants with single ventricle, unobstructed pulmonary blood flow, and transposed great arteries after PA banding, particularly in the presence of aortic arch obstruction [5, 15]. Whether this is linked to PA banding or is an inevitable consequence of the embryologic matrix from which this set of cardiac anomalies arises is unknown. Because the subaortic stenosis is generally in the form of a restrictive VSD, which is usually of a muscular variety, ascribing this to the generalized hypertrophy that PA banding produces has been a popular explanation for other investigators [5, 6]. Outflow obstruction ordinarily will occur within the first 3 years of life in the vast majority of these children. It provides the substrate for the subsequent development of severe hypertrophy of the dominant ventricle, the implications of which are important for an ultimate Fontan or ventricular septation procedure in terms of candidacy for the operation or operative risk [1-3, 16].

The explanation for this increased risk is perhaps related to changes in the compliance characteristics of the hypertrophied ventricle, susceptibility of the hypertrophied ventricle to ischemia at the time of operation, and "masked" elevation of the pulmonary vascular resistance

Table 4. Operative Data and Early Outcome^a

that occurs in spite of adequate PA banding. The hypertrophied ventricle is at risk for ischemic changes and subsequent fibrosis on the basis of differences in coronary blood flow dynamics (diminished cross-sectional area of coronary vascular bed relative to volume of myocardium [17]) as well as differences in metabolic capacity (diminished ratio of mitochondrial mass per cell mass [18] or diminished mitochondrial function [19]). Further, recovery from global ischemia of the hypertrophied ventricle is worse than for a normal ventricle and predisposes to systolic and diastolic dysfunction postoperatively [20], resulting in elevated systemic and pulmonary vascular resistances after Fontan procedures. Thus, the prevention or relief of subaortic stenosis is a critical issue in these patients.

The definition of subaortic stenosis or narrowing of the VSD in this setting is important, as is its early recognition. By the time a large systolic gradient exists between the dominant ventricle and the ascending aorta, development of severe ventricular hypertrophy will have occurred. One way to identify this early is to define the presence of subaortic stenosis as a low resting gradient (>10 mm Hg) [3, 5]. This may become more evident when measured under the provocation of a β -agonist such as isoproterenol hydrochloride, a particularly sensitive method, as the VSD is nearly always muscular in type. Other methods relate the actual size of the VSD to either body size [9] or diameter of the aortic annulus or ascending aorta [3, 5]. It is possible to measure accurately the dimensions of a VSD with the refinement of current two-dimensional echocardiography. In the newborn, it is frequently difficult to accurately assess the gradient across the VSD because of low cardiac output and congestive heart failure. Therefore, measuring the size of the VSD and relating it to body surface area or aortic root area may provide a useful index to predict the subsequent development of subaortic stenosis and also provides a noninvasive means of assessment [9].

To relieve subaortic stenosis, other methods have been proposed, including the arterial switch procedure, enlargement of the VSD, and placement of an apical ventricular-aortic conduit [2, 3]. There is limited experience in performing the arterial switch procedure for patients with this set of anomalies. The arterial switch is actually a complex modification of the simpler DKS approach. Enlargement of the VSD has been the strategy employed previously by a number of groups. It has the advantage of a direct attack on the problem and has been successful. However, there are risks of injury to the conduction system because of the variability of its position in these patients with complex physiology [21], and recurrence of obstruction can occur, particularly when a straddling valve apparatus impinges on this opening and thus limits the amount of muscle that can be safely resected. Conduits from the apex of the dominant ventricle to the descending thoracic aorta have been used but have the obvious disadvantage of requiring replacement at intervals, long-term anticoagulation, or both.

Although early experience with the DKS procedure in complex TGA or single ventricle with TGA was marked by

relatively high mortality, particularly when performed in infants [3, 5, 14], recent results in an older patient population have been excellent [22, 23]. Our results corroborate those reported by others using the DKS procedure in combination with a cavopulmonary anastomosis in terms of early mortality and overall hemodynamic status postoperatively. For these infants to reach an age at which it is appropriate to perform a cavopulmonary anastomosis, however, control of pulmonary blood flow in early infancy is mandatory and was accomplished in our series with PA banding. We recognize the long-term risk and potential sequelae of this procedure in infants with single ventricle and transposed great vessels and therefore recommend early debanding and conversion to the DKS and Glenn procedures before critical subaortic stenosis and ventricular hypertrophy occur. This is reflected in the relatively early age at operation in our patient population, particularly for those who underwent the modified Glenn shunt, but also for those who had a Fontan repair at the time of the DKS procedure.

Admittedly, rather than being constructed in a prospective fashion, our therapeutic policy has evolved over the past 4 years, with a trend toward earlier performance of a DKS procedure with cavopulmonary anastomosis. Initially, the decision to intervene with the DKS procedure was delayed until there was a major gradient across the VSD, resulting in 2 patients being followed up for nearly 3 years before that procedure. More recently, however, we have adopted the policy of a planned DKS procedure at 6 to 12 months in conjunction with a modified Glenn shunt. In spite of this, a degree of ventricular hypertrophy occurred and was still present at early follow-up. It is anticipated that some of the hypertrophy will regress as the child grows.

A legitimate concern in patients undergoing the DKS procedure involves the long-term fate of the semilunar valves. Chin and associates [24] demonstrated PI of a mild degree in 24% of patients overall after PA-ascending aorta anastomosis, primarily for hypoplastic left heart syndrome. In our early follow-up, the majority of patients had some demonstrable PI, although it was trivial or mild in nearly all of them. The later follow-up echocardiograms have not demonstrated any progression of PI whatever. The ventricular end-diastolic diameter had decreased in all of these patients compared with the measurements obtained before the DKS procedure, and none of these patients are symptomatic. This may be the consequence of distortion of the proximal PA and valve where it is attached to the ascending aorta. It is important not to stretch the proximal PA at the time of the DKS operation and to use prosthetic material if necessary to augment the length of the PA [22, 23].

For those patients in whom complete correction (ie, Fontan procedure) was not planned, a bidirectional cavopulmonary, or modified Glenn, shunt was performed. This shunt has advantages over a systemic-pulmonary shunt [25, 26] in that it does not produce a volume-overloaded ventricle, is less likely to produce PA distortion, and will not produce late pulmonary hypertension. One disadvantage is the occasional occurrence of inade-

quate pulmonary blood flow resulting from unrecognized venous collaterals connecting the superior vena cava to the azygos or hemiazygos veins, thus allowing drainage of superior vena caval blood into the inferior vena cava with bypass of the lungs. There is also some risk of the development of pulmonary arteriovenous fistulas, which has been associated with extended age of the shunt. Most of these children, however, will have a Fontan repair within 2 to 3 years, and although these fistulas are reported to occur in patients after the Fontan procedure [27], this is unusual.

Is PA banding for single ventricle with TGA a procedure ready to go the way of the dinosaur [6]? It remains a relatively safe and effective means of palliation for these infants with heart failure caused by unobstructed pulmonary blood flow, particularly in the absence of subaortic stenosis at presentation. However, outflow to the aorta through the VSD will decrease and the dominant ventricle will predictably hypertrophy in this setting, as is clearly seen in our study. For this reason, the PA band must be taken down early for further palliation before oxygen saturation worsens. In fact, many of these children will maintain adequate oxygenation, as the subaortic stenosis tends to maintain the rightward balance of the right-to-left shunt by its leftward restriction. Some authors [5, 6, 8, 23] recommend performance of the DKS procedure with a systemic-pulmonary shunt during the neonatal period to avoid the disadvantages of PA banding. As noted already, however, systemic-pulmonary shunts carry risks of their own; further, this produces a volume-overloaded single ventricle. We believe that the combination of neonatal PA banding and a DKS procedure plus a Glenn shunt at age 6 to 12 months overall carries a lower risk than a neonatal DKS procedure with systemic-pulmonary shunting and should produce a good candidate for the Fontan procedure at 18 to 36 months of age.

DISCUSSION

MR BABULAH SETHIA (Birmingham, England): I congratulate you on your results. Over the last 3 years, my colleagues and I have had a similar experience. We have performed a Damus-Kaye-Stansel procedure in association with cavopulmonary connection on 6 patients. There was one death. During this time, we also have had 1 infant who died at the age of 8 months while waiting for a cavopulmonary connection. Do you think that waiting up to 2 years for a Fontan procedure is perhaps a little long for patients with this particular pathology? Would you consider performing this sort of bidirectional cavopulmonary anastomosis relatively early, particularly in view of the experience with management of hypoplastic left heart syndrome, perhaps about the age of 6 months, to reduce this risk of sudden, unexpected early death?

DR HUDDLESTON: I appreciate your comments and questions. The older infants in this study were operated on relatively early in our experience. Our policy now is to perform the modified Glenn shunt, or bidirectional cavopulmonary connection, with the Damus-Kaye-Stansel procedure at the age of 6 to 12 months, and we are leaning more toward the 6-month period. Thus, we agree that the earlier the procedure is performed, the safer it probably is.

DR HILLEL LAKS (Los Angeles, CA): I compliment you on an excellent presentation. There had been fear that if the pulmonary artery in infants or neonates is banded in the presence of subaortic stenosis, they would not be able to tolerate it. In fact, we have not seen this. Even in patients who have slight gradients and do not require an immediate Damus-Kaye-Stansel procedure and in neonates with 15 or 20 mm Hg gradients, application of the band has not aggravated the situation, and they have tolerated it well.

Our approach is similar to yours: very early placement of a band, preferably in the first few weeks of life, and then an elective Damus-Kaye-Stansel procedure combined with a bidirectional Glenn shunt. If there is any gradient at all, we like to do this early, as early as 4 months, to avoid the hypertrophy that has been associated with mortality for the subsequent Fontan procedure.

I have a few comments on the technique of doing the Damus-Kaye-Stansel procedure. We think that to try to bring the pulmonary artery directly up to the aorta will result in pulmonary regurgitation, as you experienced, and we believe it should never be brought up without a patch. We have divided our 29 patients with a Damus-Kaye-Stansel procedure into those whose band is very proximal and those whose band is very distal. In those with a very proximal band, we make a transverse incision in the aorta immediately adjacent to the top of the pulmonary artery and then create a triangular flap in the aorta above that transverse incision. Pericardium is bridged over to roof the two arteries. Only in patients with a very distal band do we make a vertical extension of that incision into the main pulmonary artery, stopping above the commissures in order not to distort the valve. I think one of

the major defects of this procedure is the potential for pulmonary regurgitation, and techniques have to be adopted very carefully to avoid that complication.

DR HUDDLESTON: That is a very good comment. I agree that stretching the pulmonary artery is going to cause problems and that prosthetic materials should be used whenever necessary. At the time of the banding procedure, I think it is good to go ahead and put the band in a relatively distal position on the main pulmonary artery, given the fact that it is very short in a 1-month old baby, and thus allow for a bit more length in the proximal main pulmonary artery to use for the Damus-Kaye-Stansel connection.

DR MARSHALL L. JACOBS (Philadelphia, PA): I congratulate Dr Huddleston and his associates for their excellent results in managing this difficult problem. I have one comment and one question. I think Drs Damus, Kaye, and Stansel would be flattered to know that the principle of associating the proximal main pulmonary artery with the aorta has found wide application. However, technically speaking, I believe that the Damus-Kaye-Stansel operation is an operation for transposition of the great arteries that also includes the interposition of a conduit between the right ventricle and the pulmonary arteries.

My question is the following: In neonates, as you said, it is very difficult, often impossible, to accurately measure the degree of obstruction between the systemic ventricle and the aorta, particularly when there is a widely patent ductus arteriosus. I suggest that in those infants with aortic arch obstruction, its presence is indicative of already existent obstruction of flow into the aorta, and that hypoplasia or underdevelopment of the arch is reflective of the presence of that lesion. In that instance (if you were convinced of the presence of subaortic obstruction), would you not associate the main pulmonary artery with the aorta in the infant as part of the initial procedure? If that were done, might you not reduce the incidence of pulmonary insufficiency that may be associated with pulmonary artery banding?

DR HUDDLESTON: Such a Norwood type of operation, if you would refer to it as that, subjects the patients to a relatively high operative risk, at least in our experience. The degree of obstruction, as assessed probably most accurately with echocardiograms, would weigh in our decision about which procedure to perform as the initial one. We have performed this pulmonary artery-aorta anastomosis as the initial procedure in some neonates with very similar physiology and what was considered to be severe outflow tract obstruction. Pulmonary artery banding in this situation would be a relatively high-risk procedure because it would produce obstruction to both outlets of a single ventricle. However, for less severe obstruction, we believe the relative safety of pulmonary artery banding and the risk of later mild pulmonary insufficiency outweigh the high risk of a neonatal Damus-Kaye-Stansel procedure.

Atrioventricular Canal Defect: Two-Patch Repair and Tricuspidization of the Mitral Valve

M. Hashmat Ashraf, FRCS(Eng), Zahid Amin, MD, Rajesh Sharma, MD, and S. Subramanian, FRCS(Eng)

Department of Cardiovascular Surgery, Miami Children's Hospital, Miami, Florida

Between November 1978 and May 1991, a two-patch repair with tricuspidization of the left atrioventricular valve was performed in 104 patients with complete atrioventricular canal defect. Mean age was 12 months for the 68 patients who underwent primary repair and 22 months for the 36 patients who had previous pulmonary artery banding. Eleven patients died within 30 days of operation and 4 died late. Reoperation was carried out in 2 patients. Eighty-six patients were in sinus rhythm after operation. One patient required a permanent pacemaker

for complete heart block. Follow-up data for 1 to 13 years are available in 80 of 89 survivors (90%). Actuarial survival at 13 years is 81% and event-free survival is 92%. Seventy-six patients are in New York Heart Association class I and 4 in class II. Postoperative echocardiogram of these patients showed minimal or no mitral regurgitation. The advantages of this technique are preservation of valve integrity, durable mitral valve repair, and rare reoperation or heart block even in younger patients.

(*Ann Thorac Surg* 1993;55:347-51)

Mitral regurgitation and reoperation remain the two most important complications in patients undergoing repair of complete atrioventricular (AV) canal defect [1-4]. Successful surgical repair must include competence and durability of the mitral valve and elimination of reoperation [5]. We report here our experience with the repair of complete AV canal carried out using a two-patch technique in 104 consecutive patients between November 1978 and May 1991. The results, the durability of the repair, freedom from patch dehiscence, reoperation, complete heart block, and left ventricular outflow tract obstruction are analyzed.

Material and Methods

Between November 1978 and May 1991, 104 patients underwent repair of AV canal defect using a two-patch technique at Children's Hospital of Buffalo and more recently at Miami Children's Hospital. Thirty-six patients had undergone previous pulmonary artery banding with ligation of a patent ductus arteriosus, and 68 patients underwent primary repair. At the time of definitive repair, age ranged widely from 5 months to 5.5 years. Twenty-one patients were less than 1 year old, 42 between 1 and 2 years, and 41 older than 2 years.

Mean age was 12 months at primary repair and 22 months in banded patients. Associated cardiac anomalies were present in 40 patients. These were patent ductus arteriosus in 24 patients, atrial septal defects in 10, valvar pulmonic stenosis in 2, double mitral valve orifice in 2, bicuspid aortic valve in 1, and left superior vena cava in 1 patient. All patients had preoperative cardiac catheterization, angiocardiology, and echocardiography.

Presented at the Twenty-eighth Annual Meeting of The Society of Thoracic Surgeons, Orlando, FL, Feb 3-5, 1992.

Address reprint requests to Dr Ashraf, Department of Cardiovascular Surgery, Miami Children's Hospital, 6125 SW 31 St, Miami, FL 33155.

The mitral valve was fully competent in 26 patients, mildly regurgitant in 50, moderately regurgitant in 21, and severely regurgitant in 7 patients as evaluated by preoperative angiocardiology. The repair was done using a two-patch technique described by us [6]. The operations were performed on conventional cardiopulmonary bypass and cold potassium cardioplegia. In infants, deep hypothermia with circulatory arrest was used. The ventricular component was closed using a Dacron patch and the atrial component was closed with a pericardial patch. The common AV valve was sandwiched between these patches without closing the "cleft," which resulted in a trifoliate left AV valve. The configuration of the right AV valve component was not considered to be critical. The competence of the left AV valve was tested by injecting saline solution into the left ventricular cavity. If the competence of the valve appeared to be compromised by the cleft, the cleft was progressively closed, completely if necessary. In 11 patients who had residual mitral regurgitation, closure of the cleft resulted in restoration of competence. In 93 patients, valves were tricuspidized and found to be fully competent.

Results

Early Deaths

Eleven patients died within 30 days of operation while in the hospital. Three patients died of grade IV pulmonary vascular obstructive disease, 3 of severe mitral regurgitation, 2 of intractable arrhythmia, 1 of postoperative hemorrhage, 1 of low cardiac output syndrome, and 1 of aspiration pneumonia.

Late Deaths

Four patients died in the follow-up period: congestive heart failure developed in 2, 1 died of hemorrhage at

Fig 1. Actuarial survival (numbers of patients at risk are above the survival line). (E = early death.) (Reference: Berkson J, Gage RP, Mayo Clin Proc 1959).

reoperation for replacement of mitral valve, and in 1, patch dehiscence was found at autopsy.

Postoperative Rhythm

In the early postoperative period, 86 patients were in normal sinus rhythm and 17 in junctional rhythm with good hemodynamics. Complete heart block developed in 1 patient and necessitated placement of a permanent pacemaker.

Reoperation

Two patients required reoperation. One died of hemorrhage in the postoperative period after replacement of the mitral valve, and the other patient had mitral valve repair with good result.

Follow-up data for 1 to 13 years are available in 80 of 89 survivors. Patients who were lost to follow-up were mostly from outside the country. Seventy-six patients are in New York Heart Association class I and 4 in class II. The actuarial probability of survival at 13 years is 81% (Fig 1).

Comment

Repair and Mitral Competence

Rastelli-type repair has the potential drawbacks of mitral regurgitation and patch dehiscence [7-9]. The Rastelli repair requires division of the common anterior and posterior leaflets and a single patch to close the atrial and ventricular components. The divided leaflets are resuspended and the cleft of the anterior leaflet of the mitral valve is closed [12]. Division of leaflet and resuspension results in loss of valve tissue; closure of the cleft results in restricted mobility of the newly created anterior leaflet. The single Dacron patch creates the potential for hemolysis in the presence of residual regurgitation.

Carpentier's [11] studies showed that after the repair of

AV canal the mitral valve should be trifoliate. However, creation of trileaflet mitral valve as described by Carpentier requires extensive leaflet mobilization and chordal resection. This may not be necessary because most of these valves are competent preoperatively. These concerns led us to develop the two-patch repair of AV canal with tricuspidization of the left AV valve at Buffalo Children's Hospital in November 1978. We continued using this procedure in all patients at Buffalo Children's Hospital and more recently at Miami Children's Hospital. A two-patch repair with complete closure of the cleft was reported by Trusler [12]. In our technique, no portion of the valve leaflet or any chordal attachment is divided to preserve the integrity of the bridging leaflets. While the Dacron patch is attached to the ventricular crest, sutures are passed between the chordae of the AV valve. This maneuver avoids the necessity of dividing any chord. The left AV valve is sandwiched between the two separate patches used to close the ventricular and the atrial components of the defect. The mitral "cleft" is not sutured, because the tricuspidized mitral valve is fully competent and complete closure of the "cleft" may reduce the orifice area, rendering the valve stenotic and partially immobilizing the new anterior leaflet. This important fact has been emphasized recently by other authors [13, 14]. Recent anatomic observations have further clarified the surgical anatomy and emphasized the trileaflet configuration of mitral valve in AV canal defects [15, 16].

Associated Secundum Atrial Defect

Early in our experience, the tissue between the secundum atrial septal defect and primum defect was divided, which resulted in distortion of the AV valve geometry and necessitated reconstitution of this bridge. At present, if the exposure is adequate, this bridge of tissue is not divided and both defects are covered with a single pericardial patch.

Reoperation

Reoperations have been reported for mitral valve incompetence, patch dehiscence, and residual ventricular septal defect. In this series, using the two-patch technique we have achieved a fully competent mitral valve in all surviving patients with only two reoperations for mitral regurgitation. Because the AV valve is competent in most patients preoperatively, preservation of the valve geometry at the time of repair should assure full postoperative competence.

This can be achieved by accurately assessing the height of the valve, anchoring the valve to the septal patch without any distortion, and maintaining mitral and tricuspid continuity. Sandwiching the AV valve between the ventricular and atrial patches provides a buttressing effect to the valve, which prevents sutures cutting through the valve leaflets, minimizing the chance of dehiscence. This load-distribution reinforcement suture technique was experimentally shown by Katz and colleagues [17] to eliminate dehiscence.

Fig 2. Two-patch repair of atrioventricular canal. Black circle indicates the area of penetrating bundle, which is avoided.

Heart Block

In this series most patients were in sinus rhythm immediately after operation or returned to sinus from junctional rhythm within the first week. Seventeen patients remained in junctional rhythm with stable hemodynamics. Complete heart block necessitating placement of a permanent pacemaker developed in only 1 patient. To eliminate the risk of damage to the conduction tissue at operation, the bare area of the ventricular crest is consciously avoided, especially underneath the inferior bridging leaflet at its insertion, which is the position of the penetrating bundle. No suture is placed here, and when this point is reached while attaching the ventricular patch, a deliberate "jump" is made into the fibrous tissue of the valve annulus. By placing tension on this continuous suture, the Dacron patch is crimped under the posterior leaflet, thereby eliminating any risk of residual ventricular septal defect. The coronary sinus is retained in the right atrium as the suture line of the atrial patch is placed on the left side of the sinus (Fig 2).

Left Ventricular Outflow Tract Obstruction

Because of the deficiency of atrioventricular septum, the left ventricular outflow tract is malformed. Therefore, potential for left ventricular outflow tract obstruction exists in the majority of hearts with AV canal defects [18, 19]. Before repair, the geometry of the AV valve is tested by injecting saline solution into the left ventricle. By using two separate patches, the height of anchorage of the mitral valve to the ventricular patch at the level of the superior bridging leaflet can be accurately judged and this potential complication avoided. In those defects where the superior bridging leaflet is tethered to the crest of the septum with short chordae, the risk of left ventricular

outflow tract obstruction is increased, as emphasized by Chang and Becker [19]. We have encountered this situation in four hearts and have divided the tethered chords to obtain exposure of the subaortic area, which was enlarged by placement of the ventricular patch to avoid this complication.

Staged Repair

Our policy has been to perform pulmonary artery banding and ligation of patent ductus arteriosus in smaller infants, less than 5 kg in body weight (36 patients), who were in intractable heart failure and in patients who were not otherwise suitable to undergo primary repair, eg, patients who belong to the Jehovah's Witness faith with low hemoglobin. The mortality after complete repair in this subset of patients was 8%. Previous pulmonary artery banding was not an incremental risk factor for mortality. In this series, 36 of 104 patients have undergone pulmonary artery banding with ligation of patent ductus arteriosus when present, without any mortality. This experience is similar to the experience of other observers [20-22]. Furthermore, in the past, the examination by one of us (S.S.) of nonsurgical autopsy specimens of hearts with complete AV canal from infants less than 3 months of age showed that the valve tissue is friable, thin, and diaphanous, hence not well suited for repair. We therefore continue to offer pulmonary artery banding to symptomatic infants less than 3 months of age.

Pulmonary Vascular Obstructive Disease

In our early experience, 3 patients died of grade IV pulmonary vascular obstructive disease. This degree of pulmonary vascular obstructive disease was not anticipated because of inadequate preoperative evaluation. These patients were all older than 1 year of age at repair and had not been banded. Lung biopsy in older patients with questionable operability may help in selection for repair. Younger age at primary repair has not been a risk factor for death or reoperation in this series. Twenty-one patients less than 1 year of age had an operative mortality of 4.7%, 42 patients between 1 and 2 years had an operative mortality of 14%, and 41 patients older than 2 years had an operative mortality of 9.7%. Newfeld and associates [23] reported the incidence of advanced pulmonary vascular obstructive disease during the first year of life in patients with complete AV canal defect and noted intimal fibrosis (grade 3 changes) between age 6 months to 1 year. Whenever feasible, primary repair should be carried out earlier, preferably by 6 months of age, before the onset of pulmonary vascular obstructive disease.

Follow-up data showed that severe mitral regurgitation did not develop in the survivors. We believe that the use of two separate patches maintaining the continuity of mitral and tricuspid components, accurate reconstruction of a trileaflet mitral valve, and suspending the valve at an appropriate height eliminate potential complications of left ventricular outflow tract obstruction and patch dehiscence. The event-free actuarial survival was 92%; the events considered were reoperation and complete heart block (Fig 3). This compares favorably with other recent

Fig 3. Actuarial event-free survival (numbers of patients at risk are above the survival line).

reports showing a higher incidence of reoperation and heart block [4, 24].

Summary

In summary, the intermediate-term result of the two-patch repair of AV canal has been satisfactory. This technique has the advantage of preserving valve tissues and valve integrity, providing durable mitral valve competence with rare dehiscence, reoperation, or heart block even in younger children.

DISCUSSION

MR JAROSLAV F. STARK (London, England): I enjoyed your presentation. I would like you to clarify your statement about preserving the valve tissue and chordae. Do you refer to the anterior leaflet only or do you always preserve all valve tissue and all chordae to both the anterior and posterior leaflets? Professor Carpentier, when he originally described the technique, mentioned that division of some secondary and tertiary

chordae to the posterior leaflet is often necessary. We ourselves often divide some chordae to the posterior leaflet when there are short and dense chordae under the posterior leaflet to obtain better exposure and avoid the conduction mechanism.

My second comment is about keeping the left-sided AV valve as a tricuspid valve. Since we started using this technique we had to reoperate on several children who at the time of the operation

had a competent valve, did very well in the immediate postoperative period, but a few years later came in with severe left-sided AV valve incompetence. At the time of reoperation the incompetence was through the septal commissure (cleft). Closing the commissure (cleft) completely cured the problem. Currently we always close the septal commissure with interrupted stitches pledgeted with pericardial pledgets but make sure that we do not cause left-sided AV valve stenosis. I believe that this is the current practice of many congenital heart surgeons.

DR ASHRAF: In this series the chordae and the leaflet tissue were not divided, for both the anterior and posterior leaflets. The needles were passed back and forth to attach the ventricular patch. The only time any chordae were divided was at the superior bridging leaflet when the chordae were tethered and the subaortic area could not be visualized properly. Those were the only few occasions in which the tethered chordae were divided.

To answer your second question, before closing the atrial patch, we test the mitral valve by injecting saline solution into the left ventricle; if the cleft appears to be the cause, we progressively put in interrupted stitches, and see how competency is achieved. Of 104 patients, only 11 patients required closure of the cleft; 93 patients did not require closure of cleft, and we had only two reoperations with a 13-year follow-up.

DR JOSEPH J. AMATO (New Hyde Park, NY): Doctor Ashraf, I enjoyed your presentation. Just to clarify, preoperatively you showed that there were 21 patients with moderate incompetence.

Are you saying that in those 21 patients with moderate valvular incompetence these mitral valves became competent without placing sutures in the mitral leaflets? We usually repair the valve, as Mr Stark previously mentioned, not completely in most all of our patients. Did you have some incompetence in those 21 patients without suture repair?

DR ASHRAF: No, we did not. The competence of the valve was tested in the operating room, and until full competence was achieved, the operation was not over. It required a few more stitches, but hardly ever complete closure. Only 11 patients required full closure of the cleft.

DR AMATO: Doctor Ashraf, I believe you previously pointed out that you only had to put a few stitches in only a few patients. I just cannot see how the 21 incompetent valves in these patients could become competent without adding some sutures.

DR ASHRAF: Once the AV valve is supported between the patches, it does become competent.

DR JOHN W. HAMMON, JR (Winston-Salem, NC): This issue appears to be one that is being discussed a fair amount. I would like to take a straw vote. Those surgeons here who do AV canal surgery, if you routinely or almost routinely repair the so-called cleft, raise your hand; if you do not routinely repair the cleft, raise your hand. It appears that the repairers are in the majority, and perhaps discussions like this may help clarify this issue.

Double-Lung Transplantation in Children: A Report of 20 Cases

Dominique Métras, MD, Hani Shennib, MD, Bernard Kreitmann, MD,
Jean Camboulives, MD, Laurent Viard, MD, Michel Carcassonne, MD,
Roger Giudicelli, MD, Michel Noirclerc, MD, and the Joint Marseille-Montréal Lung
Transplant Program

Hôpital Ste. Marguerite, Marseille, France; La Timone Children's Hospital, Marseille, France; and Montréal Général Hospital,
Montréal, Québec, Canada

In the last 3½ years, we have performed 20 double-lung transplantations in children between 7 and 16 years old (mean age, 13 years). One patient had primitive bronchiolitis obliterans and the other 19, cystic fibrosis. Eight patients were operated on in an emergency situation, 7 of them requiring ventilator support before transplantation. The procedures were en bloc double-lung transplantation in the first 11 patients with separate bronchial anastomoses in 10, and sequential bilateral lung transplantation in the later 9 patients. There were no operative deaths. Two patients died in the hospital on postopera-

tive days 37 and 73, and there were four late deaths, which were due to infection, rejection, and bronchiolitis obliterans. The acceptable incidence of airway complications, the improvement in lung function of survivors, and the acceptable midterm survival make double-lung transplantation an acceptable alternative to heart-lung transplantation in children. However, in very small children, heart-lung transplantation may be preferable because of the size of the airway anastomoses at risk.

(*Ann Thorac Surg* 1993;55:352-7)

The technique of bilateral lung transplantation has evolved from en bloc heart-lung transplantation to en bloc double-lung transplantation and finally to sequential bilateral lung transplantation. Although heart-lung transplantation originally was advocated for all types of parenchymal diseases and for pulmonary vascular disease either isolated or caused by Eisenmenger syndrome, it has now been restricted to irreparable or irreversible heart defects associated with pulmonary disease. Single-lung transplantation is now advocated for many parenchymal and pulmonary vascular diseases, and double-lung transplantation is advocated when both lungs have to be removed, in particular for septic lung diseases such as cystic fibrosis or bronchiectasis.

Lung transplantation has been done mostly in adult patients. The difficulty of looking after children with end-stage heart or lung disease and the uncertainty about the long-term outcome of the allografts have raised doubts about the usefulness of performing lung transplantation in children. It has been suggested [1] that children will experience more episodes of rejection, both acute and chronic, which will result in graft attrition and a disappointing long-term outcome. In the world experience, heart-lung transplantation has been by far the most frequent procedure reported for lung transplantation in children [2] and in patients with cystic fibrosis in particular [3]. In 1988 in Marseille, we started a double-lung transplant program in children with cystic fibrosis [4].

This article reports our experience and our intermediate-term results in 20 consecutive pediatric patients undergoing double-lung transplantation in the combined Marseille-Montréal lung transplant program.

Material and Methods

Between May 1988 and December 1991, 58 children were accepted for transplantation, including some very severely ill patients who required ventilation. Few children (only 3) were denied inclusion on the waiting list. Twenty-two patients (40%, 22/55) died while awaiting transplantation because of a lack of donors. During the same period, 20 patients underwent bilateral lung transplantation.

There were 11 girls and 9 boys. The average age at transplantation was 13 years (range, 7 to 16 years). The average weight was 25 kg (range, 14 to 56 kg). The indication for transplantation was cystic fibrosis in 19 patients and primitive bronchiolitis obliterans in 1 patient.

The nutritional status of most patients was poor, their growth pattern being well under the normal range for their age. Twelve patients were in stable condition and 8, in severe condition at transplantation. These 8 patients were in intensive care and receiving intravenous inotropic support necessitated by secondary right ventricular failure; 7 of them were on a ventilator with nasotracheal intubation for 1 day to 21 days before transplantation. The patient having ventilator support for 21 days had a tracheostomy 3 days before transplantation.

Age of the donors ranged between 4 and 20 years (mean age, 11 years), and weight ranged between 17 and 70 kg (mean weight, 37 kg). After the first few patients, little

attention was paid to size and weight matching between donor and recipient, and more attention was given to the size of the chest. The criterion used for size matching was the circumference of the thorax at the nipple level, a variation of 10% being accepted.

The lungs were procured as part of a multiorgan harvesting, the technique including crystalloid cardioplegia and a single flush of 4°C Euro-Collins solution in the pulmonary artery after an infusion of prostaglandin E₁. The ischemic time ranged from 2 hours 15 minutes to 7 hours (mean time, 4 hours $\pm$ 1 hour 30 minutes). In the first 11 patients, the en bloc double technique [5] was used with a tracheal anastomosis in the first patient and bilateral bronchial anastomoses in the following 10 patients [6, 7]. In the last 9 patients, bilateral single-lung transplantation [8] was performed through a bilateral transverse thoracotomy. In none of the patients was omentopexy or any wrapping of the airway anastomoses done. All operations were performed with cardiopulmonary bypass, moderate hypothermia, and a beating heart except during the left atrial anastomosis in en bloc double-lung transplantation, where cardioplegia was used.

The immunosuppression regimen included induction with rabbit antithymocyte globulin (2.5 mg/kg) for 7 to 14 days and triple immunosuppression with cyclosporin A, azathioprine, and corticosteroids. Cyclosporin A was given preoperatively, intraoperatively, and postoperatively as a continuous intravenous administration until oral administration became possible after approximately 2 weeks. We aimed at a residual level of 150 to 250 ng in serum or 300 to 500 ng in total blood. The steroids were given intraoperatively (4 ng $\cdot$ kg⁻¹ $\cdot$ d⁻¹) and withheld thereafter for 2 to 3 weeks in the initial experience. In the last 7 patients, corticosteroid administration was started earlier at 0.6 mg/kg and tapered to 0.2 mg/kg after 4 to 6 months. Azathioprine was given at 2 mg/kg for the first week and then reduced to 0.5 to 1.5 mg/kg to obtain a white blood cell count in the range of 4,000 to 7,000/ μ L (4.0 to 7.0 $\times$ 10⁹/L).

The postoperative antibiotic regimen included a double or triple association to obtain synergy and was usually identical to the pretransplantation treatment. The antibiotics commonly used, based on the most recent assessment of bacterial sensitivity in vitro, were a penicillin (ceftazidime, imipenem), an aminoglycoside (amikacin sulfate, tobramycin sulfate), and a quinolone (ciprofloxacin). Antifungal prophylaxis was also instituted for 1 month (amphotericin A, 0.2 mg/kg). Rejection monitoring included routine endoscopies and biopsies, the former being started after day 5 for inspection of the airway anastomoses. Biopsies were done systematically every week, then every month after the second month, and then every 3 months in the following year. Subsequently, routine lung function studies, computed tomographic scans, and scintigraphs were performed. Rejection episodes were treated with intravenous pulse steroid therapy (17 mg $\cdot$ kg⁻¹ $\cdot$ d⁻¹) and OKT3 when resistant to steroids. Four episodes of rejection were treated with OKT3.

Results

There were no operative deaths and two in-hospital deaths. One involved a 12-year-old patient with severe multiorgan failure preoperatively (coma, renal failure, artificial ventilation). This patient died on postoperative day 37 of multiorgan failure, infection, airway dehiscence, and cerebral anoxia. The other patient died of posttransplantation lymphoproliferative lung disease 73 days after transplantation. This patient had multiple episodes of rejection requiring augmentation of immunosuppression and repeated pulse steroid therapy. He also had one course of OKT3.

There were four late deaths. One patient with cystic fibrosis but otherwise in excellent condition died of acute bronchopneumonia 4 months after sequential bilateral lung transplantation. The causative organism was unknown, as the death occurred in a remote community hospital where no bacterial investigation was done. The other three deaths were due to bronchiolitis obliterans at 1 year, 1 year 3 months, and 1 year 6 months. In 2 of these patients, it was associated with chronic infection and repeated episodes of rejection. Both patients also had a permanent left main bronchial stent.

The postoperative course was difficult, with most patients requiring mechanical ventilation for 1 day to 54 days (mean duration, 16 days). Eight patients needed a temporary tracheostomy. The duration of ventilator support after transplantation did not correlate with the time of ischemia or the need for preoperative ventilation. Four patients had renal failure requiring peritoneal dialysis. Patients had insulin-dependent diabetes, discovered during a pulse of intravenous steroid therapy. Two patients had a temporary unilateral diaphragmatic palsy. Cardiac function, even when impaired preoperatively, always improved. Fifteen patients required prolonged inotropic support after transplantation until the right ventricle recovered normal function.

Postoperative Infections

The duration of the initial course of antibiotics ranged from 10 to 35 days based on the negativity of bronchial secretions. Pulmonary infections caused by *Pseudomonas aeruginosa* developed in 5 patients during their initial hospital course. No patient died of this infection, but in 2 it became chronic, associated with bronchiolitis obliterans, and the patients died at 13 and 19 months.

A late infection developed in 6 patients. One of them died at 4 months. A *Pseudomonas aeruginosa* infection developed in 5 patients, 2 of whom were cured. In the other 3, the infection was chronic and recurrent. A cytomegalovirus lung infection developed in 5 patients and was diagnosed by bronchoalveolar lavage (4 patients) or by transbronchial biopsy (1 patient). All were successfully treated by DHPG.

Airway Complications

Bronchoscopy under short general anesthesia, at bedside when necessary, was well tolerated and uneventful. The patient with a tracheal anastomosis had development of an anastomotic stricture 3 months after transplantation. This was treated with one session of laser therapy. Nine-

teen patients had 38 bronchial anastomoses at risk. Twelve patients had simple or uneventful healing, whereas 7 had airway complications. One patient had bilateral necrosis and dehiscence (the patient who died 37 days after transplantation). Two patients had bilateral bronchomalacia, predominant on the left side, and needed a permanent left main bronchial stent. Both later died of bronchiolitis obliterans and superimposed rejection and infection.

Left main bronchomalacia developed in 4 patients, necessitating one permanent and three temporary endobronchial stents. All stents were the Dumon Silastic (Dow Corning, Midland, MI) stents [9]. In the initial experience, bronchial complications were found to be related to preoperative ventilation and younger age of recipients (less than 10 years). In the recent experience, and particularly with sequential bilateral lung transplantation, bronchial healing was generally uneventful.

Rejection Episodes

In the first month, 16 patients had one or two rejection episodes (0.9 episode per patient). At 1 year, rejection occurred at the rate of 0.2 rejection episodes per patient. After 1 year, there were no acute rejection episodes.

Bronchiolitis Obliterans

Bronchiolitis obliterans developed in 6 of 14 patients followed up for more than 6 months, an incidence of 42.9%. This diagnosis was based on a progressive, irreversible decline in pulmonary flow measurements. Histologic diagnosis was accomplished in 3 patients by transbronchial biopsy and in 3 by open lung biopsy. Three of the 6 died of infectious complications secondary to bronchiolitis obliterans. One patient underwent retransplantation after a year. Before the heart-lung retransplantation, he received ventilator support for 66 days. One year after retransplantation, he is in excellent condition. Two patients are awaiting retransplantation 2½ years after initial double-lung transplantation. Eight patients are leading a normal life, but 2 of them are considered to have moderate and stable bronchiolitis obliterans.

Lung Function

After transplantation, there was significant improvement in forced expiratory volume in 1 second from $25.5\% \pm 2.1\%$ predicted before transplantation to $75\% \pm 5.8\%$ predicted at 3 months, $95.3\% \pm 7.4\%$ predicted at 6 months, and $87.4\% \pm 10.8\%$ predicted at 1 year ($p > 0.01$ compared with pretransplantation values for all three periods) (Fig 1). The mild decline observed at 1 year is related to the development of bronchiolitis obliterans in 3 patients. Similarly, the forced vital capacity increased significantly from $41.4\% \pm 2.3\%$ predicted before transplantation to $84.5\% \pm 4.8\%$ predicted at 3 months, $101.2\% \pm 4.8\%$ predicted at 6 months, and $99.1\% \pm 9.2\%$ predicted at 1 year ($p < 0.01$ compared with pretransplantation value) (see Fig 1).

Follow-up

Overall, 13 patients, including 1 patient who underwent retransplantation, are doing well or reasonably well 3 to

Fig 1. Changes in lung function during the first year after operation. Data are shown as percent predicted. (FEV1 = forced expiratory volume in 1 second; FVC = forced vital capacity.)

45 months after transplantation, this including the patient with retransplantation. The actuarial survival is 70% at 3 years (Fig 2). Nine of the 13 have resumed a normal life with considerable development and weight gain. They attend school, and some have taken up hobbies or sports requiring a high level of activity such as alpine skiing, tennis, soccer, or gymnastics.

Comment

The recent success of isolated lung transplantation reported by the Toronto group was followed by an explosion in the number of transplantations performed worldwide. Current registry data [2] indicate that as a consequence of the increase in the number of single- and double-lung transplantations performed, heart-lung transplantation has dwindled. Although single-lung transplantation can be suitable therapy for patients with nonseptic parenchymal or vascular lung disease, replacement of both lungs is thought to be essential for any patient with evidence of pulmonary infection. Contrary to the experience in adults, initial reports on pediatric lung transplantation have not been encouraging, with mortality attributed to a high incidence of acute rejection, airway complications, and infections [1].

In this series, we report our experience with bilateral lung transplantation in children less than 17 years of age. Bilateral lung transplantation without the heart was performed as the primary graft in all patients with parenchymal disease and a normal heart or a temporarily failing heart. The relatively low morbidity observed in this pediatric lung transplant experience may reflect the fact that children are generally more tolerant of surgical complications and the fact that the bacteria they harbor have not necessarily acquired the multiresistance to antibiotics observed in the adult population with cystic fibrosis. In addition, the absence of operative mortality in this pediatric group, which consists almost exclusively of patients with cystic fibrosis, may reflect the lack of extensive

Fig 2. Actuarial survival curve for 20 children undergoing double-lung transplantation. Number of patients at risk is in parentheses.

thoracic adhesions and hence the reduced bleeding and the lower cardiopulmonary bypass time compared with adults. Heart-lung transplantation was used as the second procedure for a recipient of a double-lung transplant in whom bronchiolitis obliterans developed. The choice of a heart-lung transplant rather than a redo double-lung transplant was made because the patient had had en bloc double-lung transplantation, and we did not wish to leave segments of bronchus from 2 donors.

During the first 6 months, pediatric recipients of lung transplants appeared to experience the same complications seen in adults. Infection, rejection, and airway complications are not uncommon. Our methods of surveillance and investigation of pulmonary complications are no different from those in adult patients. We use fiberoptic bronchoscopy liberally when indicated. Transbronchial biopsy and bronchoalveolar lavage are routinely used at the time of bronchoscopy to rule out rejection or infection.

Children are at the highest risk of the development of bronchopneumonia during the first month after transplantation. In this series, five episodes were observed to occur in the first month in 20 patients at risk. In the subsequent 6 months, only three episodes were noted in 14 patients at risk. These data suggest that as the incidence of rejection decreases and the doses of immunosuppression are lowered, and the patient is away from the hospital environment, the risks of infection decrease.

Pediatric recipients of lung transplantation are also at highest risk of development of acute rejection during the first months. We noted 18 episodes in 20 patients at risk during this period. This is no different from the experience observed in other pediatric organ transplant programs or in adult patients [10]. All episodes of rejection except for three were responsive to pulse steroid therapy. OKT3 was effective in treating steroid-resistant rejection on three occasions. In 1 child who received relatively high and repeated doses of steroid therapy for the treatment of rejection posttransplantation lymphoproliferative disorder developed and the patient died 73 days after transplantation. This 5% incidence of lymphoproliferative disorder is similar to that reported in adult patients [11].

The frequency and severity of airway complications were within normal limits and have decreased substantially in the more recent experience with the bilateral single-lung technique. We therefore believe that airway complications are no different in children than they are in adults. Although our numbers are too small to confirm such an observation statistically, we believe that younger children should be considered for a tracheal anastomosis rather than bronchial anastomoses. The age and weight of this group are not defined. Whether this is incorporated as part of a heart-lung or double-lung procedure remains to be determined. More recently, we have performed a successful heart-lung transplantation in a 6-year-old boy weighing 12 kg with cystic fibrosis (not included in this study) and employed a tracheal anastomosis for this small patient.

Pulmonary function testing in our pediatric lung transplant series indicates significant improvement in forced expiratory volume in 1 second and forced vital capacity immediately after transplantation. There is continual improvement up to 6 months after operation, at which point lung volumes start to plateau. A slight drop in the percent predicted forced expiratory volume in 1 second and forced vital capacity observed at 1 year in our series may reflect the development of bronchiolitis obliterans in some patients. These objective findings indicate that bilateral lung transplantation in the pediatric population results in improvement in lung function and hence an expected better overall performance by these children.

Among the 14 patients followed up for longer than 6 months, bronchiolitis obliterans developed in 6. We believe this incidence is no different from what can be expected in adults with our current methods of immunosuppression: cyclosporine, azathioprine, and low doses of prednisone. Three of the 6 patients are in stable condition with no further drop in forced expiratory volume in 1 second and are now studying and working full time. Two other patients with marked dyspnea and limited function are awaiting transplantation. The only patient in this series who has had retransplantation has regained normal function and is symptom-free 9 months after receiving a heart-lung transplant. Whether retransplantation should

be considered for patients with development of bronchiolitis obliterans in the primary grafts and which technique of retransplantation to use are controversial. As most patients with end-stage bronchiolitis obliterans will harbor fungal or bacterial infection, it is almost certain they would require replacement of both lungs. Whether heart-lung or double-lung retransplantation is chosen will likely be addressed in the next few years as more patients with bronchiolitis obliterans are seen for retransplantation.

The issue of the growth potential of transplanted lung allografts in children is not resolved. There is, however, experimental evidence to suggest that lung allografts show an increase in airway diameter and lung volumes with age [12]. Hislop and associates [13] reported an increase in both number and size of alveoli after allogeneic single-lung transplantation in animals. Whether growth potential differences between donor and recipient bronchi will occur and lead to the risk of anastomotic stenosis must still be determined. Within the limited period of observation in this study, we can report normal clinical and radiologic thoracic development and the absence of airway complications, findings attributed to the development of donor lungs.

Finally, the results in the severely diseased patients needing artificial ventilation and inotropic support before transplantation were not different from those in the other patients. This was true with reference to all variables, such as survival, complications, and difficulty of postoperative management. Therefore, we believe that mechanical ventilation per se before transplantation should not be considered a contraindication to transplantation. Multi-organ failure before transplantation, however, is a definite contraindication, and our patient who died on day 37 would not have been a candidate now for transplantation.

We conclude from this study that bilateral lung transplantation is a valid option for the treatment of children with end-stage lung disease. Currently, sequential bilateral lung transplantation is our procedure of choice in all patients with septic lung disease. Heart-lung transplantation is rarely needed and should be restricted to patients with combined heart and lung disease or when bronchial anastomoses are likely to be at risk for the development of complications, as in retransplantation and in younger children with smaller airways. Although pediatric bilateral lung transplantation can result in good intermediate-term survival and function, research directed toward prevention and treatment of bronchiolitis obliterans is needed to achieve better long-term survival.

Addendum

Since this report was written, 2 patients have undergone retransplantation for bronchiolitis obliterans 2 and 2½ years after double-lung transplantation. Both had heart-lung transplantation and died after operation. One died of an oversized graft and 1 of inability of the heart to resume normal function. The second patient was in multiorgan failure while on the ventilator for 4 weeks and had severe metabolic disturbances that may have caused the failure of an otherwise uneventful operation. Since then, a 14-year-old patient has had a successful sequential bilateral lung transplantation for cystic fibrosis. We have therefore updated the actuarial survival curve (Fig 3).

Fig 3. Updated actuarial survival curve for 21 children undergoing double-lung transplantation. This curve represents that in Figure 2 revised after two unsuccessful retransplantations. The low survival rate at 3 years may not be significant because of the small number of patients at risk. Number of patients at risk is in parentheses.

We gratefully acknowledge the following surgeons, intensivists, pediatricians, and pulmonologists who have actively participated in the program: Marie-Ange Silicani, MD, Adrienne Pannetier, MD, Olivier Garbi, MD, Pierre Geigle, MD, Jean-Yves Marty, MD, Monique Badier, MD, Louise Garbe, MD, Jean-François Dumon, MD, Jean-Pierre Chazalotte, MD, David S. Mulder, MD, and Christo I. Tchervenkov, MD.

We also thank Françoise Moucadet for secretarial assistance.

DISCUSSION

DR R. MORTON BOLMAN III (Minneapolis, MN): I enjoyed your presentation very much, Dr Métras. My colleagues and I have also had some experience with retransplantation in children. In children with cystic fibrosis in whom obliterative bronchiolitis develops, is single-lung retransplantation adequate, or, in the likelihood of bronchiectasis and infection developing in the contralateral lung, would bilateral replacement be better? I notice you did a heart-lung transplantation in 1 child. Why did you do that?

DR MÉTRAS: In our experience, all these patients with cystic fibrosis have chronic infection, and we would not recommend single-lung transplantation. The problem is we do not know yet what to do—another sequential bilateral lung transplantation or a heart-lung transplantation. This is, of course, debatable.

As for the patient who underwent heart-lung transplantation, we chose that procedure because the first operation was a double-lung transplantation by the technique of Dr Cooper. We did not want the patient to have bronchus from 3 people, 1 recipient and 2 donors, so we decided to do heart-lung transplantation.

DR DONALD C. WATSON JR (Memphis, TN): I enjoyed your presentation very much. It reminds me of why people often go into cardiothoracic surgery, that is, to take basic and clinical research to solve new or difficult problems. You mentioned a limited donor supply, as did Dr Spray yesterday. I have one observation and two questions.

About 2 years ago, my associates and I were asked to evaluate a 4½-year-old girl with primary pulmonary hypertension. She ultimately was put on the recipient list. She waited until the parents asked, "Why wait? We can help." Ten months ago, her mother donated a right lower lobe, and today that young girl is out of the hospital and back in school after a complicated course and recovery from a lymphoproliferative disease related to Epstein-Barr virus.

This isolated case was pushed by circumstances, but the pediatric patient does present some unique options. My two questions are the following: (1) Do you think that lung donation from a living relative is a real option, not necessarily for our particular scenario but for patients with cystic fibrosis? and (2) Will the type of scenario I described encourage a critical review of the organ donation base that we currently use?

DR MÉTRAS: I think the shortage of donors favors bilateral lung transplantation in patients with cystic fibrosis instead of heart-lung transplantation. In France, the demand for hearts is so great that it is very difficult to find a heart-lung donor. However, once the heart has been donated, obtaining the lungs is relatively easy. I think the tendency to use bilateral lung transplantation instead of heart-lung transplantation is going to increase.

As for your lobar transplant, I think it is a very nice success and I congratulate you for your beautiful experience, but I have some doubts. I believe it would be a lifesaving procedure only for a certain time, because it has been shown that multiplication and growth of the alveoli are finished after the age of 8 years. One lobe from an adult cannot develop in a child except by emphysema, and I do not see how such a lobe can make a normal lung for a growing child. Nevertheless, I am sure that in some cases this would be a lifesaving procedure that could be followed later by replacement with a whole lung.

DR G. ALEXANDER PATTERSON (St. Louis, MO): Professor Métras, that was a beautiful presentation, and you are to be congratulated for those results, particularly considering that children with cystic fibrosis represent the overwhelming majority of your patients.

I have two questions. First, we heard yesterday from Dr Spray that their pediatric group uses cardiopulmonary bypass routinely in all cases, and you have said the same. Can you explain why you use bypass to do sequential bilateral lung transplantation in these children and whether you have encountered any difficulty because of the use of bypass?

Second, I was struck by the lack of septic complications in your patients with cystic fibrosis. What type of prophylaxis do you use? Do you treat the sinuses preoperatively, and what antibiotic regimen is used?

DR MÉTRAS: To answer your second question first, all the patients have the sinuses treated. There were, in fact, 12 patients who had complications, some of them very severe. Concerning the antibiotic regimen, I am a surgeon; the intensivists use antibiotics the names of which I do not even know, and there are always new antibiotics. In the postoperative prophylaxis three or four antibiotics are used. This is the best answer I have.

DR PATTERSON: Is it true that there was only one perioperative death resulting from sepsis?

DR MÉTRAS: The patient died, but not of sepsis. Sepsis was one of several of his problems. It is true that no patient in our experience died of postoperative infection only.

As for your first question on cardiopulmonary bypass, I am happy that you asked about this, because I think the use of cardiopulmonary bypass in the pediatric population is harmless and even useful. These children had no pleural adhesions. This is one characteristic of cystic fibrosis in children in our experience: there are very few adhesions. So cardiopulmonary bypass does not add any more risk of hemorrhage, and the recent patients bled very little postoperatively. We use cardiopulmonary bypass because most often the donor is a remote donor. At the appropriate time after a donor has been found, we put the patient on bypass, remove the two lungs, and prepare everything for the anastomoses. Then when the lungs arrive, we can rapidly perform the three anastomoses. We think this is a quicker, simpler procedure than to wait for the donor and then try to do sequential bilateral single-lung transplantation without bypass.

DR HANI SHENNIB (Montreal, Que, Canada): Perhaps I can follow up on this question. In regard to Dr Patterson's questions as to what antibiotics we use and why we do not have a high incidence of sepsis in these patients, I think it is necessary to remember that what we are dealing with in this particular study is a population of children. We tend to see a higher incidence of multiresistant *Pseudomonas* infections in adults compared with children. Most of these children would have a combination of antibiotics that would be effective. We tend to use aggressive doses of aerosolized tobramycin or Coly-Mycin in the patients with cystic fibrosis (we put almost all our patients on aerosol therapy) in addition to intravenous antibiotics based on the multisensitivity in vitro.

Retrograde Continuous Warm Blood Cardioplegia: Maintenance of Myocardial Homeostasis in Humans

Steven R. Gundry, MD, Nan Wang, MD, David Bannon, MD, Robert E. Vigessaa, MD, Clifford Eke, MD, Simon Pain, MS, and Leonard L. Bailey, MD

Division of Cardiothoracic Surgery, Department of Surgery, Loma Linda University School of Medicine, Loma Linda, California

Recent clinical reports have suggested that continuous delivery of oxygenated warm blood cardioplegia through the coronary veins (retrograde cardioplegia) produces good myocardial preservation during aortic cross-clamping. No data exist, however, about actual myocardial metabolism/homeostasis during retrograde warm blood cardioplegia. We studied 100 consecutive patients undergoing coronary artery bypass grafting, aortic valve replacement, or both who received retrograde continuous warm blood cardioplegia (4:1 dilution) during aortic cross-clamping for 54 to 174 minutes. We measured pH, oxygen tension, carbon dioxide tension, HCO_3^- , base excess, and oxygen content of the inflow cardioplegia and the blood egressing from coronary arteries during each arteriotomy for bypass grafting (arteries act as postcapillary veins with retrograde cardioplegia) or the left and right coronary orifices during aortic valve replacement. We also measured these variables from the coronary sinus effluent 1 minute after release of the aortic cross-clamp. Retrograde cardioplegia flow ranged from 50 to 250 mL/min (mean flow, 150 mL/min). All patients were maintained at normothermia during bypass. A total

of 460 samples were analyzed (4.6 per patient). Neither the duration of aortic cross-clamping nor the artery sampled affected myocardial blood gases. The pH dropped from 7.41 ± 0.05 for the inflow cardioplegia to 7.32 ± 0.1 when sampled from coronary arteries, and the oxygen tension fell from 181 ± 25 to 28 ± 5 mm Hg, respectively. Carbon dioxide tension rose from 31.0 ± 4.1 to 41.4 ± 9.8 mm Hg. Coronary sinus blood gases 1 minute after cross-clamp removal showed no acidosis or oxygen debt. These results indicate that (1) myocardial homeostasis is preserved by retrograde continuous warm blood cardioplegia during normothermic aortic cross-clamping for up to 3 hours in humans; (2) normal myocardial metabolism and oxygen uptake can be maintained solely by retrograde cardioplegia in the arrested heart, eliminating oxygen debt and ischemia; and (3) unlike experimental models, the arrested human heart is *very* active metabolically. Further application of this new clinical technique appears warranted, provided appropriate monitoring is used.

(*Ann Thorac Surg* 1993;55:358-63)

The ability of surgeons to preserve myocardial viability during periods of aortic cross-clamping has existed since the earliest days of clinical open-heart operations in the 1950s. Prompted by the laboratory successes of Blanco and associates [1], Lillehei and his colleagues [2] successfully operated on the aortic valve using continuous retrograde perfusion of the beating, warm human heart through a catheter placed in the coronary sinus. Even in 1954, the idea of perfusing oxygenated warm blood into the myocardium through the coronary veins to preserve the heart was not new, having been described as early as 1898 by Pratt [3].

By 1959, however, despite 4 years of successful clinical application, retrograde continuous warm perfusion of the heart was largely abandoned in favor of antegrade intermittent hypothermic perfusion or cardioplegia [4]. Re-

cently, owing largely to improved delivery systems and the recognition of the consequences of myocardial ischemia such as reperfusion injury, retrograde continuous warm perfusion of the heart has been reintroduced into the clinical arena [5, 6]. Despite several reports on the successful human application of this technique, little experimental or clinical work is available that describes the effectiveness of this technique in preventing myocardial ischemia.

To understand how continuous retrograde perfusion of oxygenated blood cardioplegia might preserve myocardial viability, the interrelationship of the coronary venous and arterial anatomy must be considered (Fig 1). The coronary venous system not only connects with myocardial capillaries but also interconnects with other coronary veins by way of veno-venous collaterals and with the ventricular and atrial cavities directly through the thebesian vessels. So rich are these venous connections that only 25% of blood retroinfused into the coronary sinus traverses the capillaries, the remainder exiting the myocardium through the venous channels without providing nutrient

Presented at the Twenty-eighth Annual Meeting of The Society of Thoracic Surgeons, Orlando, FL, Feb 3-5, 1992.

Fig 1. Coronary venous and arterial drainage patterns. Dark arrows show retroperfused blood flow patterns.

blood flow [7]. The retroperfused blood cardioplegia that does traverse the capillaries, in general, uses the coronary arteries to egress from the myocardium. Thus, in continuous retrograde cardioplegia, sampling the coronary artery effluent would be expected to give a most reliable measure of myocardial oxygen extraction, acid-base status, and homeostasis. The testing of this hypothesis in 100 consecutive patients undergoing myocardial revascularization, valve replacement, or both forms the basis of this report.

Material and Methods

The study comprises all adult patients having myocardial revascularization, valve replacement or repair, or a combination of these from February 1991 to the present on the service of the primary author (S.R.G.). Myocardial protection was provided by continuous retrograde infusion of warm (37°C) blood cardioplegia (4:1 dilution) administered through a flexible catheter with a manually inflated distal balloon and with constant monitoring of coronary sinus pressure (Gundry RSCP catheter; DLP, Inc, Grand Rapids, MI). The technique of insertion of this catheter has been previously described [8]. Essentially, it entails placing the catheter into the coronary sinus through a pursestring suture in the high right atrium and directing the catheter using a flexible stylet.

Induction of myocardial arrest was accomplished by the infusion of warm blood cardioplegia (4:1 dilution) at 250 to 300 mL/min using a final KCl concentration of 27 mEq/L into the coronary sinus RSCP catheter until arrest was achieved and then switching to continuous infusion of a 4:1 blood cardioplegia mixture with a KCl concentration of 9 mEq/L at 110 to 150 mL/min. Whenever a coronary arterial blood gas analysis showed a pH of less than 7.30, cardioplegia flow was increased by 50 mL/min up to 300 mL/min. Assessment of myocardial perfusion was made visually by noting engorged red veins and blue arteries and by noting the issuance of dark blood from arteriotomies or coronary orifices; also, a low-pressure alarm was placed on the coronary sinus pressure line (DLP, Inc) and set to sound when coronary sinus pressure was less than 15 mm Hg.

Samples for blood gas analysis were taken from the inflow cardioplegia line and from each coronary arteriotomy at the time of bypass graft placement, and from the coronary artery ostia in the case of aortic valve replacement. They were repeated at least every half hour. At the termination of aortic cross-clamping, cardioplegia infusion was stopped and the balloon deflated. One minute later, a final blood gas sample was taken from the coronary sinus through the retrograde catheter, which was still in place, and compared with a blood gas sample taken from the arterial line from the bypass pump. All blood gas samples were analyzed for pH, oxygen tension (P_{O_2}), carbon dioxide tension (P_{CO_2}), HCO_3^- , base excess, and oxygen content. Comparison was made between the inflow cardioplegia and the blood egressing from the coronary arteries as a measure of myocardial metabolism and between the inflow cardioplegia and the coronary sinus blood after release of the cross-clamp as a measure of oxygen debt. All patients were maintained at 37°C during sampling.

Results

The results of the blood gas analyses for the first 100 patients studied are shown in Table 1. A total of 460 samples were analyzed (4.6 ± 1 samples per patient). The inflow cardioplegia reflected a 4:1 mixture of perfusion blood and Roe's solution, which supposedly had been buffered to a pH of 7.45 before delivery to the operating room but was consistently slightly acidotic on delivery (base excess -3.7 ± 2.6 and pH 7.41 ± 0.05). Blood gases from the coronary artery effluent, representing blood that had traversed the myocardial capillaries, had a mean pH of 7.32 ± 0.1 with a base excess of -4.7 ± 2.6 . Postcapillary pH ranged from a low of 7.20 to a high of 7.55. Coronary sinus blood pH after cross-clamp release was 7.38 ± 0.1 with a base excess of -0.4 ± 3.0 versus a pH of 7.42 ± 0.08 in the arterial line.

The P_{O_2} of the inflow cardioplegia was 181 ± 25 mm Hg, which fell to 28 ± 5 mm Hg when measured in the coronary artery effluent. This value rose to 37 ± 6 mm Hg when measured in the coronary sinus after

Table 1. Summary of Blood Gas Analyses^a

Variable	Cardioplegia	Coronary Artery Effluent	Coronary Sinus 1 Minute After ACC Release
pH	7.41 ± 0.05	7.32 ± 0.1	7.38 ± 0.1
P_{O_2} (mm Hg)	181 ± 25	28 ± 5	37 ± 6
P_{CO_2} (mm Hg)	31.0 ± 4.1	41.4 ± 9.8	40.5 ± 4.5
HCO_3^-	19.3 ± 1.5	20.5 ± 1.8	23.1 ± 1.9
Base excess	-3.7 ± 2.6	-4.7 ± 2.6	-0.4 ± 3.0
O_2 content	7 ± 2	4 ± 2	5 ± 2

^a Data are shown as the mean $\pm$ the standard error of the mean.

ACC = aortic cross-clamp; O_2 = oxygen; P_{CO_2} = carbon dioxide tension; P_{O_2} = oxygen tension.

cross-clamp release versus 180 ± 21 mm Hg systemically. The P_{CO_2} of the inflow cardioplegia was 31.0 ± 4.1 mm Hg and rose to 41.4 ± 9.8 mm Hg in the coronary artery samples, similar to the value of 40.5 ± 4.5 mm Hg measured in the coronary sinus later. Little change in bicarbonate ion was detected, which increased from 19.3 ± 1.5 (inflow) to 20.5 ± 1.8 (postcapillary outflow) and measured 23.1 ± 1.9 in the coronary sinus after unclamping. Oxygen content of the inflow cardioplegia was 7 ± 2 , which decreased to 4 ± 2 in the coronary artery effluent, a value similar to that for the coronary sinus blood.

Cross-clamp times ranged from 54 to 174 minutes. No difference in blood gases could be detected based on duration of cross-clamping. Nor could a relationship be found in myocardial blood gases based on the region of the heart served by a coronary artery, although the right coronary and posterior descending coronary arteries had slightly lower pHs and PO_2 s than other regions.

In several hearts, notably those with hypertrophy, postcapillary blood pH appeared to correlate directly with cardioplegia flow. As an example, take the case of a 76-year-old man with left ventricular hypertrophy who was undergoing a bypass procedure. The initial blood gas analysis of the inflow cardioplegia showed a pH of 7.40, P_{CO_2} of 31 mm Hg, PO_2 of 176 mm Hg, base excess of -4.5 , and oxygen content of 7.3. At a flow of 125 mL/min, the initial left anterior descending coronary artery blood had a pH of 7.20, P_{CO_2} of 53 mm Hg, PO_2 of 45 mm Hg, base excess of -6.7 , and oxygen content of 4.9. When the inflow cardioplegia rate was increased to 180 mL/min, the subsequent blood gas values in that artery changed to a pH of 7.36, P_{CO_2} of 33 mm Hg, PO_2 of 35 mm Hg, base excess of -5.6 , and oxygen content of 4.6, thus indicating normalization of pH and P_{CO_2} but a still high oxygen extraction.

When the pH of the coronary arterial blood gas fell to less than 7.30, flows were increased up to 300 mL/min until a pH of greater than 7.30 was obtained. Increased flows were required in 48 of the 100 patients.

Comment

Retrograde continuous warm (or normothermic) cardioplegia for myocardial protection during aortic cross-clamping differs little from that used by Lillehei and co-workers [2] nearly 40 years ago with the exception that potassium is now added to the perfusate to arrest the heart. This addition was made secondary to the experimental findings that most of the energy savings afforded the heart by cardioplegia come from mechanical arrest and that little additional benefit is gained by cooling [9].

Extrapolating from these experimental findings, Salerno and co-workers [6] and Lichtenstein and associates [10] clinically showed that good myocardial protection could be achieved by continuous perfusion of the heart with potassium blood cardioplegia in either an antegrade or retrograde fashion. The former, because of its complicated delivery system and the need to shut off cardioplegia or snare coronary arteries to construct anastomoses, was and remains clinically difficult to apply. However,

since our introduction in 1987 of transatrial insertion of coronary sinus catheters, facile retrograde delivery of cardioplegia makes retrograde warm cardioplegia an everyday clinical reality [8]. Whether retrograde continuous warm cardioplegia allows normal myocardial homeostasis and prevents myocardial ischemia in humans was not known heretofore. The degree of metabolic activity of the warm, arrested human heart was also unknown, despite conjecture based on animal experiments. Last, the effect of using retrograde warm cardioplegia solely without an initial antegrade dose was unknown.

The results of our study clearly indicate that the human heart is fully capable of using blood perfused retrogradely through the coronary veins to maintain myocardial homeostasis. This, in itself, is not surprising, as retrograde perfusion of oxygenated blood without cardioplegia was shown by Lillehei and colleagues [2] in 1956 to maintain myocardial viability during short periods of aortic cross-clamping. Hammond and associates [11] demonstrated in dogs similar myocardial "venous" PO_2 s to those of our patients during 1 hour of retrograde coronary sinus perfusion at 37°C in the beating heart, but they noted better functional recovery, particularly of the right ventricle, if inflow perfusion temperature was lowered to 26°C .

Our study demonstrates that blood gas measurements of blood egressing from the heart through the coronary arteries closely approximates normal coronary sinus blood gas values. What is perhaps surprising is the high degree of oxygen extraction and therefore metabolism of the arrested human heart. This is contrary to reports of myocardial metabolism in animals by Buckberg [12], Bernard [9], and their co-workers that suggest that the normothermic, arrested heart requires about 90% less oxygen than the beating, working heart. Because coronary blood flow is approximately 4% of total cardiac output, normal coronary blood flow usually is 200 to 300 mL/min. Thus, a warm, arrested heart should require only 10% of this flow or 20 to 30 mL/min to maintain homeostasis. As only 25% of retrograde perfusion through the coronary veins traverses the myocardial capillary bed, it would be proper to suppose that four times as much flow would be needed retrogradely to maintain cellular needs, or 80 to 120 mL/min. Although in many patients this does appear to be the case, our study uncovered many patients, particularly those with left ventricular hypertrophy, who required 250 to 300 mL/min to maintain homeostasis and to prevent myocardial ischemia.

Our study suggests that the degree of metabolic activity of some human hearts, unlike their experimental animal counterparts, may be quite high and must be met. This indicates that retrograde continuous warm cardioplegic protection of the myocardium is not guaranteed, but rather its effectiveness must be monitored. In this study, direct sampling of postcapillary blood gases appeared to be a simple and effective method of accomplishing this goal. Other simple methods, however, such as continuously monitoring myocardial PO_2 , usually cannot detect adequate myocardial delivery of substrate but merely detect the presence or absence of infused cardioplegia, in

the same way as the low-pressure alarm on the coronary sinus transducer in our study.

Last, our study demonstrates that myocardial energy needs can be met entirely by retrograde delivery of warm cardioplegia without the need for antegrade cardioplegia. As we [8] have previously shown with retrograde intermittent cold cardioplegia, antegrade cardioplegia imposes an unnecessary step and complicates an otherwise simple procedure. Moreover, it stretches the imagination a bit to believe that in a 2-hour cross-clamp period, a 2- to 3-minute dose of antegrade cardioplegia would have much influence on myocardial protection. Also, in redo operations, antegrade cardioplegia may impose dangers of its own in embolizing atheromatous debris from old vein grafts [13].

In conclusion, based on blood gas analysis of inflow and outflow cardioplegia samples in 100 patients, we have shown that retrograde continuous warm cardioplegia is capable of maintaining myocardial homeostasis and preventing myocardial ischemia in humans for up to 3 hours of aortic cross-clamping. Further, we have demonstrated variability in the metabolic needs of the warm, arrested human heart that sometimes seem at odds with and are greater in amount than experimental literature might suggest. During retrograde warm cardioplegia, the surgeon must ensure that the delivery of cardioplegia blood flow and volumes are sufficient to meet myocardial energy needs. In this study, this was easily achieved by sampling blood gases from arteriotomies. Finally, this study establishes that retrograde warm cardioplegia does not need an antecedent antegrade dose of cardioplegia to provide myocardial protection.

Much basic clinical research must be completed to understand the nature of retrograde delivery of cardioplegia to the capillary level and how to consistently measure the adequacy of this delivery. Although this study demonstrates the effectiveness of the technique of retrograde warm cardioplegia, it also imposes on the surgeon the necessity to monitor and confirm the adequacy of myocardial protection. At this stage in its development, we recommend continuous monitoring of coronary sinus

pressure, a standby low-pressure alarm, and intermittent sampling of coronary artery effluent for pH, P_{CO_2} , and PO_2 , with adjustment of retrograde flows accordingly.

DISCUSSION

DR SIDNEY LEVITSKY (Boston, MA): I have a question that I think concerns many of us, and that is the problem of right heart versus left heart preservation during retrograde continuous warm blood cardioplegia. There is concern that much of the right heart coronary flow drains out through the thebesian veins, thus avoiding the coronary sinus. At New England Deaconess Hospital, we started using retrograde continuous warm blood cardioplegia in April 1991. Not infrequently, we have observed the absence of blood flow in the posterior descending coronary artery after arteriotomy in patients with a total occlusion of the right coronary artery. Nevertheless, these patients have a benign postoperative course with no evidence of right heart failure. Have you noticed any differences in oxygenation or pH, for example, between the right posterior descending or right marginal coronary vessels as opposed to the left-sided vessels?

DR GUNDRY: That is an excellent question and one that concerned us a great deal as we embarked on warm cardioplegia. We did notice a difference in samples taken from the right coronary artery or the posterior descending coronary artery in that they invariably had a lower pH and lower oxygen content. The oxygen tensions were often in the range of 10 to 15 mm Hg. However, when the data for the 100 patients were analyzed, none of these figures reached statistical significance compared with the other areas sampled in the heart. Using transesophageal echocardiography, we have looked at the function of almost all of these hearts, and much to our surprise, even with "lousy" right coronary artery blood gases, the right ventricular function of these hearts has been superb, better than I would have expected. But, yes, there seems to be a lower pH in those vessels and much more avid oxygen extraction. The flow is not as good to the right side.

DR GEORGE E. CIMOCHOWSKI (Wilkes-Barre, PA): That was an elegant presentation, Dr Gundry. My colleagues and I also have been interested in coronary effluents, and in the past 6 months, we have studied a small series of patients. We frequently turn off the retrograde flow for a short time, about 5 to 10 minutes, and did so in each of the study patients. We *never* turn it off in a patient with a hypertrophied ventricle.

We studied coronary effluents from the left anterior descending coronary artery. These were always measured after the last anastomosis, which in each case was the internal mammary artery. Initially we were timid; we stopped at 5 to 7 minutes and measured the pH and the PO_2 . The pH was quite good, 7.37. After we got a little more bold, we stopped it for 10 minutes, and our mean pH was 7.33, but there certainly was a range—7.11 to 7.52. We think that it is “probably” safe to stop retrograde flow for a short time. In our experience and probably in yours, the hypertrophied left ventricle with coronary artery disease is a flag.

I say that because there is a lot of variation in blood flow retrograde in the coronary sinus system. It is not simply a matter of giving cardioplegia in the coronary sinus and seeing it come out the coronary artery. An example is our recent case of an 85-year-old woman with coronary artery disease who was having a double-valve operation. During the mitral valve replacement, we noticed clinically there was good flow coming from the aorta. However, when we did the aortic valve replacement, we did not see good flow from the coronary ostia. We even gave antegrade cardioplegia and used a catheter with a manual inflating device. At 5 mL, we did not increase flow from the coronary ostia, and the patient died of low cardiac output. We subsequently took the heart to the autopsy suite, and at 6 mL in the balloon with the manual inflating device, there was free flow back and forth into the right atrium. With the self-inflating balloon, there was massive regurgitation.

Have you seen similar patients in whom the coronary sinus is so large that our equipment does not seem to cause the flow to go only retrograde?

DR GUNDRY: Yes, indeed. We have been impressed with the ability of the coronary sinus of a warm heart to expand. Unlike a cold heart, in which the coronary sinus and its surrounding fat tissue become quite rigid, during warm cardioplegia, the coronary sinus is really free to expand much like many other thin-walled veins. In fact, during valve replacement on several large hypertrophied hearts, we have used as much as 10 mL of air in an operator-inflated balloon to seal the coronary sinus. This is particularly important if you use transesophageal echocardiography, in that the anesthesiologist can put a Doppler probe across the coronary sinus proximal to the balloon. He or she can tell you how much air to inject into the balloon to seal the coronary sinus by looking at blood leaking around the balloon. It is often very dramatic.

Your point about hypertrophied hearts is extremely well taken. We have recently submitted an abstract to the Western Thoracic Surgical Association issuing a warning about hypertrophied hearts and some redo operations. This is a very dangerous area in retrograde continuous warm cardioplegia. We have got to be very careful and know a lot more about it before we can endorse it wholeheartedly.

DR CIMOCHOWSKI: We have done studies of the amount of blood flow coming out of the aorta retrogradely. As you raise the heart for the various maneuvers, by the time you get to the circumflex, you may have a 50% to 75% reduction in blood flow coming out the aorta. So all the answers are not in yet.

DR GUNDRY: That is correct. Even holding the heart to press on a circumflex area will dramatically change what comes out of that artery. Your assistant has to learn how to hold the heart in a slightly different way so as not to compress those veins.

DR PAUL T. FRANTZ (Roanoke, VA): I enjoyed your presentation very much. Based on our experience, the heart can tolerate intermittent ischemia during aerobic warm arrest. This experience involves 457 patients, 361 of whom had coronary bypass operations.

Our early technique was similar to that used in Toronto. In normothermic patients, we used intermittent antegrade and continuous retrograde cardioplegia while performing proximal and distal grafts with the aortic cross-clamp on.

Because of technical problems associated with retrograde catheters, we began using an intermittent antegrade technique. The appearance of multiorgan failure mentioned earlier led us to switch from normothermic to hypothermic systemic perfusion. One of our current techniques is to use intermittent antegrade cardioplegia, turning the solution off for 10 to sometimes 15 minutes. The proximal anastomosis is done after each distal graft. In some patients we use intermittent antegrade and intermittent retrograde cardioplegia, and in these situations, all the proximal grafts are done after the distal grafts have been completed.

There were 167 patients in whom we used the antegrade and retrograde technique. There were nine deaths and three myocardial infarctions in this group. Three patients required the balloon pump. The deaths were due to multiorgan failure (1), isolated ventricular fibrillation (2), preoperative myocardial infarction (1), sepsis (1), cerebrovascular accident (2), and hypertrophic cardiomyopathy (2). There was one preoperative massive myocardial infarction.

An intermittent antegrade technique was used in 194 patients. In this group there were only one death and three myocardial infarctions. Four patients required the balloon pump.

In our experience, the heart tolerates periods of interruption in cardioplegic flow. Based on your experience with the continuous retrograde technique, how do you explain this observation?

DR GUNDRY: I appreciate your comments and those of the last discussants about technique. As we are all practicing cardiac surgeons, we know that the heart can tolerate imperfection. We practice it nearly every day, unfortunately. We also know that a heart operated on 15 years ago, for example, that of a 45-year-old man undergoing placement of a couple of bypass grafts, could tolerate a cross-clamp across the aorta every 15 minutes, and the patient could come off bypass extremely easily. Unfortunately, I do not see those patients anymore; the cardiologists see them.

We are talking about applying a technique of preservation to a completely different stratum of patients, patients who cannot get a heart transplant because there are no donors; these patients have an ejection fraction of 0.15. As Dr Swain said a few minutes ago, it is one thing to take an ejection fraction of 0.60 and lose a third of it; the patient would leave the operating room smiling. When you take an ejection fraction of 0.20 and lose a third of it, the results include a left ventricular assist device, balloon pump, and death. So why tolerate any myocardial ischemia in a heart that if it loses three myocytes the patient may not leave the operating room alive? Hearts can tolerate ischemia; we prove that every day. However, we are trying to develop a technique where there is absolutely no ischemia. We are not quite there yet, but we are pretty close.

DR ROBERT A. GUYTON (Atlanta, GA): I have first a rebuttal to Dr Frantz. I think it is a dangerous and inappropriate leap of

faith to go from continuous warm cardioplegia to intermittent warm cardioplegia. I believe that is a backward step. There is abundant theoretical and experimental evidence that after 2 or 3 minutes of ischemia, myocardial damage begins. This is seen in nuclear magnetic resonance machines, in myocardial creatine kinase depletion, and in adenosine triphosphate depletion; repeated stunning of the heart causes metabolic damage. Because you can get away with something in the operating room does not mean that this is what is best for the heart in all situations, and I recommend that we not adopt intermittent warm cardioplegic techniques.

Second, Dr Gundry, I question and perhaps reject your hypothesis that sampling the coronary artery samples the heart because a hypoperfused region contributes very little to the sampled blood. If most of the blood is going to myocardium that is perfused, then that is what you are going to be sampling in the coronary artery. You do not sample the maybe 15% of the heart that is getting 2% of the cardioplegia because that 2% makes up such a small volume of what you are sampling. I think that to look at metabolism in a global way, you must sample globally and collect in a controlled situation the entire effluent.

DR GUNDRY: Thank you very much. I strongly echo your statements about the intermittent warm technique. As for sampling, what we tried to do was look at a regional sample as represented by a coronary artery and to compare that with the effluent from either a left coronary artery ostium or right coronary artery ostium. We could not find any difference between a regional area and a more global area. So I think an individual coronary artery sample can tell you what is happening in that region of interest at that point. A more global sample, such as that from a left main artery, can tell you more about what is happening to the heart as a whole.

Again, these are hypotheses. We hoped we proved or suggested we proved the hypothesis, but I take your point.

DR SAMUEL V. LICHTENSTEIN (Toronto, Ont, Canada): I congratulate you on an excellent study. It certainly puts some of our own concerns to rest. When Dr James Abel first introduced retrograde continuous warm blood cardioplegia in Toronto and the rest of us later adopted it, we were very concerned about the distribution of nutritive flow to the right ventricle and septum. The theory of warm heart surgery is based on the fact that electromechanical arrest reduces myocardial oxygen requirements to nearly minimal levels with little further benefit attributable to hyperthermia. You have referred to the warm arrested

heart as metabolically active. My question is, have you looked at retrograde continuous cold cardioplegia and compared its oxygen consumption with that of retrograde continuous warm cardioplegia?

DR GUNDRY: Anecdotally we have been able to do this in a very small number of patients. Because the cardioplegia is so cold, there is an extremely small drop in oxygen saturation or oxygen tension when studied across that capillary area. Whether that is because the heart is not metabolically active or much less metabolically active or because hemoglobin simply would not give up oxygen because of the cold, we cannot prove in a human model; we are trying to think of a way to do it.

Nevertheless, if you look at the basis of calculation and try to look at myocardial mass and oxygen consumption per mass, experimental studies suggest that myocardial metabolism of a warm, arrested heart drops to about 10% of that of the normal working heart. If you calculate even a 25% capillary crossing of retrograde flow, that is a nutrient blood flow of 25%; in most hearts the calculations work out well; about 125 to 150 mL of flow should meet metabolic demands. But in about half of the hearts, we had to go to higher flows, contradicting what calculations from animals tell us should have been adequate to meet the heart's demands. These flows are with the balloons inflated. So there is a lot we do not know.

DR CONSTANTINE E. ANAGNOSTOPOULOS (New York, NY): My colleagues and I abandoned the use of isolated experimental retrograde perfusion some years ago because we observed myocardial edema. I have not heard about any methods you use at present to assess whether you have myocardial edema with a higher flow, for example, echocardiography. Furthermore, I understand that you have tried to use your samples as regional samples, but perhaps if you used pulmonary artery vents and tied the superior and inferior venae cavae, you would be able to have better representation of a global specimen.

DR GUNDRY: Your points and contributions are well taken. We have looked at intermittent retrograde cardioplegia and low-flow retrograde cardioplegia in an experimental model in edema, and like the Emory group, we could find no increase in myocardial edema. Apparently, based on their report earlier today, they also could not confirm myocardial edema with their continuous high-flow retrograde method. It does not seem to be a clinical concern.

Optimal Pleurodesis: A Comparison Study

Michael A. Bresticker, MD, Junichi Oba, MD, Joseph LoCicero III, MD, and Rodney Greene, BS

Sections of General Thoracic Surgery, Northwestern University Medical School, Chicago, Illinois, and Harvard University, New England Deaconess Hospital, Boston, Massachusetts

With the resurgence of thoracoscopy, there is renewed interest in less invasive methods of pleurodesis. We wished to compare in an animal model a variety of methods suggested in reports. The purpose of the study was to rank the effectiveness of each procedure against the standard mechanical pleurodesis. Twenty-five mongrel dogs (weight, 25 to 35 kg) underwent bilateral thoracotomy. Each animal was randomly assigned to receive two of the following methods of pleurodesis: tetracycline, talc, mechanical abrasion, neodymium:yttrium-aluminum garnet (Nd:YAG) laser (Hereus Inc, E. Rutherford, NJ) photocoagulation, and argon beam coagulator (ABC) (Beacon Lab, Bloomfield, CO) electrocoagulation of the parietal pleura. At evaluation at 30 ± 2

days, the efficacy of pleurodesis was graded on a scale of 0 to 4, with 0 representing a complete absence of pleural symphysis and 4 the adhesion of more than one lobe to both the chest wall and mediastinum. Mean grade and standard deviation of each method were: talc, 3.0 ± 0.67 ; mechanical, 3.0 ± 0.82 ; tetracycline, 2.3 ± 1.4 ; ABC, 1.5 ± 0.97 ; and Nd:YAG laser, 0.7 ± 0.95 . Both the talc and mechanical methods were superior to either the Nd:YAG laser or the ABC ($p < 0.01$). In this study, neither the Nd:YAG laser nor the ABC proved efficacious in producing pleurodesis. Talc poudrage is the only method of pleural symphysis comparable with mechanical abrasion.

(*Ann Thorac Surg* 1993;55:364-7)

Pleurodesis is commonly performed for recurrent or persistent pneumothoraces or chronic pleural effusion. The current definitive treatment includes thoracotomy, bleb resection, and mechanical pleural abrasion or pleurectomy. Although effective, open pleurodesis subjects the patient to the morbidity of thoracotomy, which includes general anesthesia, postoperative atelectasis, pneumonia, and the unknown long-term functional effects of dividing large muscle groups. Furthermore, patients with chronic pleural effusion often are at high risk for a major operation owing to preexisting malignancy or cardiopulmonary disease. Recently, the resurgence of thoracoscopy has led to a renewed interest in less invasive methods of pleurodesis. Reported alternatives have included talc poudrage [1, 2], instillation of various chemical sclerosing agents [3, 4], and thoroscopically guided pleural scarification with either the neodymium:yttrium-aluminum garnet (Nd:YAG) laser [5] or the argon beam coagulator.

To date, the majority of studies on methods of pleurodesis have been limited to clinical trials in which the efficacy of pleurodesis was determined by the rate of recurrence of pneumothorax or pleural effusion. In this study, we wished to conduct a controlled comparison study of reported methods of pleurodesis by using an

animal model. The efficacy of pleurodesis for each method was then "ranked" against the standard open pleurodesis and mechanical abrasion.

Material and Methods

All animals were housed and procedures performed in the facilities of Northwestern University Medical School, Chicago, IL. Animals received humane care in accordance with the "Guide for the Care and Use of Laboratory Animals" published by the National Institutes of Health (NIH publication No. 85-23, revised 1985).

Twenty-five mongrel dogs (weight, 25 to 35 kg) underwent bilateral standard thoracotomy through the fifth intercostal space. Because thoracoscopic visualization of the entire pleural surface in the dog is difficult, thoracotomies were performed to ensure visual confirmation of adequacy of the surgical pleurodesis. The canine model was used because of the durability of the animal to withstand bilateral thoracotomies and a cavity size large enough so that all instrumentation could be used with equal facility on all parts of the pleura. Anesthesia was induced with acepromazine (0.1 mg/kg) and sodium thiamylal (4% solution, 0.5 mL/kg) and maintained with halothane.

Each animal was randomly assigned to receive two of the following methods of pleurodesis: (1) mechanical dry gauze abrasion, (2) chemical sclerosis with 500 mg of tetracycline hydrochloride, (3) talc poudrage (1 g asbestos-free talc), (4) Nd:YAG laser photocoagulation, and (5) argon beam electrocoagulation of the parietal pleura. This

Presented at the Twenty-eighth Annual Meeting of The Society of Thoracic Surgeons, Orlando, FL, Feb 3-5, 1992.

Address reprint requests to Dr LoCicero, Division of Cardiothoracic Surgery, New England Deaconess Hospital, 110 Francis St, Suite 2C, Boston, MA 02215.

totalled 10 hemithoraces per experimental group. The randomization code allowed some animals to receive the same method bilaterally. Mechanical abrasion was performed by rubbing gauze against the pleural surface until punctate hemorrhages were produced but the integrity was not disrupted. Tetracycline (0.016 g/kg) was diluted in 100 mL of saline solution and sprayed on the pleural surface. The residual fluid was not evacuated from the chest. This is a similar dose to that used clinically (0.014 g/kg diluted in 250 mL of saline solution). Talc was applied in a similar manner. A suspension of 1 g was mixed in 100 mL of saline solution and sprayed in the chest. Neodymium:yttrium-aluminum garnet laser pleurodesis was performed with a 1064-nm laser from Heu-reus Inc, E. Rutherford, NJ, set at 50 W continuous wave in a focused mode through a hand probe (2-mm spot size). Photocoagulation of the pleura overlying all accessible ribs was performed until there was gross carboniza-tion of the parietal pleura. This was done to simulate clinical situations. Mean energy applied per pleurodesis was 7,800 J. Argon beam electrocoagulation used an argon beam coagulator (Beacon Lab, Bloomfield, CO) coupled to a standard electrocautery unit. A flexible delivery catheter allowed access to the pleura overlying all visible rib surfaces. An energy setting of 35 W was used and the pleura coagulated until a black char was produced. Oper-ative time for each side averaged 1.5 hours.

In all procedures, the chest was closed over a thoracos-tomy tube, which was removed under positive-pressure ventilation at the conclusion of the operation. Lung ex-pansion (which was complete in all cases) was confirmed by postoperative roentgenogram. Buprenorphine hydro-chloride was administered every 12 hours for 48 hours for postoperative analgesia.

All animals were allowed to recover and then observed for a mean of 30 ± 2 days. After the animals were killed, a median sternotomy was performed and the efficacy of pleurodesis graded on a scale of 0 to 4:

- 0 = Complete absence of adhesions
- 1 = Periincisional adhesions only
- 2 = Adhesion of one lobe to chest wall or mediastinum
- 3 = Adhesion of more than one lobe to chest wall or mediastinum
- 4 = Adhesion of more than one lobe to chest wall and mediastinum

The use of codes at autopsy assured that the investigators were blinded as to the type of pleurodesis each animal had received.

Data were expressed as mean $\pm$ standard deviation of the mean. The paired Student's *t* test was used to deter-mine the differences between each group. A *p* value of less than 0.05 was considered statistically significant.

Results

A total of 50 pleurodesis procedures were performed on 25 animals. One animal that received Nd:YAG laser pleurodesis died on postoperative day 4. Autopsy re-

Table 1. Results of Pleurodesis

Technique	Grade ^a
Mechanical abrasion	3.0 ± 0.82
Talc poudrage	3.0 ± 0.67
Tetracycline	2.3 ± 1.4
Argon beam coagulator	1.5 ± 0.97^b
Nd:YAG laser	0.7 ± 0.95^b

^a Values are shown as mean $\pm$ standard deviation. ^b *p* < 0.01 versus talc poudrage and mechanical abrasion.

Nd:YAG = neodymium:yttrium-aluminum garnet.

vealed a massive hemothorax and a focal area of necrosis in the intercostal muscle overlying a neurovascular bun-dle. This animal was replaced. All other animals survived the procedure and recovered without complication. Ani-mals were killed at a mean of 30 ± 2 days after operation. The mean grade and standard deviation for each grade are shown in Table 1.

Talc poudrage and mechanical abrasion were equally effective in producing pleural symphysis. Both methods were significantly superior to either the Nd:YAG laser or the argon beam coagulator group (*p* < 0.01). Chemical sclerosis with tetracycline was consistently more effective in producing pleural symphysis than either laser tech-nique; however, the difference was not statistically signif-icant.

Qualitatively, the adhesions produced by talc poudrage and mechanical abrasion were more dense, requiring sharp dissection for their lysis, than those produced by the other three methods.

Comment

Spontaneous pneumothorax is one of the most common of the diseases faced by a thoracic surgeon. Typically, it occurs without warning in young, healthy males and is caused by a subpleural bleb at the lung apex. Ipsilateral recurrences are common, and the risk of recurrence in-creases with each episode, ranging from 20% after the initial episode to up to 80% after a third pneumothorax [6, 7]. Treatment with a thoracostomy tube alone results in reexpansion of the lung and some minimal degree of pleural symphysis due to pleural abrasion by the tube itself. Although this approach is effective in the majority of patients, 20% to 30% will have recurrence warranting more aggressive attempts at pleurodesis. Thoracotomy with bleb resection and mechanical abrasion is the most effective treatment but is a major surgical procedure associated with serious morbidity. Less invasive methods include the instillation of various sclerosing agents, talc poudrage, and, most recently, laser scarification of the parietal pleura. Previous studies on methods of pleuro-desis have been limited to clinical trials, which have found recurrence rates of 13% to 25% for tetracycline sclerosis [1, 8, 9], 3% to 8% for talc poudrage [1, 2], and 7% for Nd:YAG laser pleurodesis [5].

In this study we were able to assess the ability of five

different methods of pleurodesis under controlled conditions in an animal model. The dog is a large animal, which allows easy access to all of the pleural surface with current clinical instrumentation. Also, because the dog does not form adhesions well, we considered it a severe test that would give the greatest difference between techniques. Rats and rabbits have been used in some adhesion experiments because they form adhesions easily. We were concerned that all methods might produce dense adhesions and thus not afford an opportunity to distinguish among the methods.

Because this study was designed to apply directly to patients, each method was applied in a similar manner to the clinical situation. It is difficult if not impossible to control all variables in surgical techniques, so we used them as we have in humans. The surgical principles, power settings, and methods of application approximated as closely as feasible our operative technique. With the exception of Nd:YAG laser scarification, our results compare favorably with the clinical trials cited above. Talc poudrage was the only method comparable with standard mechanical abrasion in this canine model. Clinically, no sclerosing agent has been found to have a lower recurrence rate than that reported for talc.

"Closed" methods of pleurodesis fail, in part, because they do not address the underlying lung pathology, ie, pulmonary blebs. Recently, interest in thoracoscopic bleb ablation has been fueled by studies documenting the CO₂ laser's ability to seal pulmonary air leaks [10] and by clinical trials employing electrocautery [11] and laser energy [12] to coagulate pulmonary blebs. Rusch and associates [13], using a rabbit model, found the argon beam coagulator to be as effective as electrocautery in sealing pulmonary air leaks and to cause less acute tissue injury than standard electrocautery. Theoretically, any method that can successfully seal or ablate pulmonary blebs should decrease the risk of recurrent pneumothorax.

Chronic pleural effusions represent the other most common indication for pleurodesis. These patients are often elderly and have severe cardiopulmonary disease or malignant effusions secondary to end-stage cancer. Life expectancy in this group of patients is limited and recurrence of pleural effusion inevitable after simple drainage. Therefore, pleurodesis must be accomplished in the simplest, least invasive manner. Recent studies have compared sclerosis with bleomycin and tetracycline [14] as well as talc poudrage [15] for treatment of malignant effusions. As with spontaneous pneumothoraces, talc poudrage was found to be superior in preventing recurrence of malignant pleural effusion.

In this study, talc poudrage was the most efficacious closed method of pleurodesis and comparable with mechanical abrasion. Concern over the long-term safety of talc poudrage has been unfounded. Long-term follow-up studies by Lange and associates [16], Viskum and co-workers [17], and the British Thoracic Association [18] have found only a mild restrictive impairment of lung function and no increased risk of mesothelioma or lung cancer 20 to 40 years after talc poudrage for spontaneous or recurrent pneumothoraces. The incidence of recurrent

pneumothorax after talc poudrage in these studies was 2% to 3%.

In summary, we advocate simple thoracostomy tube drainage for the initial episode of spontaneous pneumothorax. The 20% to 30% of patients who have recurrence should undergo thoracoscopy with attempted bleb ablation and pleurodesis. As thoracoscopic techniques become more familiar and improve, the procedure should be able to be done under local anesthesia. Finally, patients with chronic pleural effusions would best be served by thoracoscopy and talc poudrage to limit the number of procedures in a debilitated patient with an often limited life expectancy.

DISCUSSION

DR RODNEY J. LANDRENEAU (Pittsburgh, PA): I want to thank Drs Bresticker and LoCicero for allowing me to discuss this report. I first would like to comment that I firmly agree with them that the most important thing in the management of the spontaneous pneumothorax is to control the underlying pulmonary pathology. I have a bit of a problem, however, with the use of talc as the means of providing pleural symphysis in situations of benign disease. I would refer to a recent article by Drs Curtis Tribble and Tom Daniel from the University of Virginia, appearing in *The Annals of Thoracic Surgery*, where they recently recommended talc poudrage for variety of clinical conditions. However, I have learned from recent discussions with Dr Daniel that he now refrains from using talc poudrage for most benign pleural disease. Talc is a very effective means of managing the malignant effusion, or malignant process, but for primary or spontaneous pneumothorax I think that this is not an appropriate application because of the intense pleuritic reaction it can cause. I furthermore agree that laser or argon beam coagulation is a relatively ineffective way of primarily handling these problems.

I have two questions for Dr Bresticker. Do you have in mind a subsequent study comparing chemical pleurodesis with bleomycin or other alternative antibiotic sclerosants, such as doxycycline, with talc as a control? Second, the advent of thoroscopic video-assisted thoracic surgery basically allows the same operation, a stapled resection of apical bullous disease and mechanical pleurodesis through the thoroscopic ports, to be accomplished with minimal operative morbidity. With the advent of this new procedure, are you still of the opinion that talc poudrage is the most effective way of handling the problem of spontaneous pneumothorax?

DR BRESTICKER: In response to the first question, we chose tetracycline primarily because it has traditionally been the most widely used. We do hope to in future studies compare bleomycin and doxycycline, which is what we use now that tetracycline is no longer available. We did not use bleomycin in this study for two reasons: because of its expense and because we did not know the systemic effects of intrapleural bleomycin in the canine model.

And it is true, in response to your second question, that as equipment and the techniques of thoracoscopy improve, mechanical abrasion could be performed through the thoracoscope, and this would supplant talc poudrage as the preferred method of pleurodesis.

DR HERMES C. GRILLO (Boston, MA): Just one word of caution. Many years ago I had very successful results with talc pleurodesis through a thoracoscope in one hospital. I later performed the same procedure in another hospital and had a high incidence of recurrence. Grabowski and Malt [1] illuminated this some years ago when they studied talc as a generic material and found it varied in composition from different sources with great variability in the power to instigate adhesions. Some talcum powder is benign whereas some other produces firm adhesions.

Intrapleural Quinacrine Instillation for Recurrent Pneumothorax or Persistent Air Leak

Heinrich M. J. Janzing, MD, Alex Derom, MD, Eric Derom, MD,
Catharina Eeckhout, MD, Fritz Derom, MD, and Marie-Thérèse Rosseel

Surgical Department and Heymans Institute of Pharmacology, University Hospital, University of Ghent Medical School, Ghent, Belgium

From 1982 to 1990, 27 patients with recurrent pneumothorax or persistent air leak (28 episodes) underwent pleurodesis with intrapleural administration of quinacrine, according to a standardized scheme. A first evaluation was done about 1 month after the intervention. In August 1990, all patients were invited for a second check-up. In 4 patients quinacrine plasma concentrations were determined. There was one early failure. No late recurrences were observed. Neither serious nor late complications were seen with our low-dose regimen. Tran-

sient fever was the only constant side effect. In contrast to other chemicals proposed for pleurodesis, quinacrine did not cause major pain. Only very low quinacrine plasma concentrations (peak, <10 ng/mL) were found. In conclusion, chemical pleurodesis with quinacrine can be considered a safe and effective treatment. The number of administrations as well as the dosage are important to prevent morbidity and recurrence.

(*Ann Thorac Surg* 1993;55:368-71)

It is claimed that patients with recurrent pneumothorax or persistent air leak should undergo a surgical intervention [1] and that, if operation should be avoided, tetracycline pleurodesis remains the alternative of choice [2]. However, intrapleural administration of tetracycline can be very painful, and surgical pleurodesis demands general anesthesia and is not without morbidity. Moreover, the production of injectable tetracycline hydrochloride for pleurodesis has been recently discontinued [3].

In 1982, we first introduced quinacrine pleurodesis at our institution as a treatment of recurrent pneumothorax or persistent air leak in patients who were in poor general condition and hence were bad candidates for surgical pleurectomy. Our initial results were very satisfactory and prompted us to use this technique for patients with pneumothorax who were referred for operation. The present retrospective study was performed because quinacrine pleurodesis is still not a widely accepted treatment for pneumothorax.

Material and Methods

From September 9, 1982, until August 25, 1990, 27 patients with persistent air leak (air leak persisting beyond 4 days despite adequate tube drainage) or recurrent pneumothorax were treated, after informed consent, with chemical pleurodesis by intrapleural administration of quinacrine hydrochloride. All patients had previously been treated by chest tube drainage.

Quinacrine hydrochloride, 100 mg dissolved in 50 mL of sterile physiological saline solution (prepared in our hospital pharmacy), was injected through the thorax

drain, which was then closed for 1 hour. Active suction (-20 cm H_2O) was then restarted. If the magnitude of the air leak did not allow the drain to be clamped, the drain was suspended as described by Almassi and Haasler [4]. Quinacrine was given once daily on 4 consecutive days. The drain was clamped 24 hours after the last injection. About 48 hours after the last injection, chest radiography was performed; if lung expansion had been maintained the drain was removed. Doses were chosen in accordance with the report of Larrieu and associates [5].

An ambulant check, including radiography of the chest, was performed about a month after therapy. Moreover, in August 1990, all patients, with the exception of patient 11 (the early failure), were invited for anamnestic, clinical, and radiological check-up. Only 24 of the remaining 26 patients could be reevaluated, because 2 patients died of causes not related to the pleurodesis; those patients, however, did not have recurrence.

In 4 patients quinacrine plasma concentrations were measured by high-performance liquid chromatography and fluorescence detection, as described by Björkman and Elisson [6].

Results

Twenty-eight episodes of pneumothorax in 27 patients were treated with quinacrine pleurodesis. Table 1 shows the patient characteristics. Seventeen patients had eighteen episodes of spontaneous pneumothorax. Among them, 6 had radiographic signs of severe emphysema and 1 (with bilateral pneumothorax) had cystic fibrosis. Quinacrine pleurodesis was performed in these patients because of a recurrence of pneumothorax in 11 and because of a persistent air leak in 7. One patient suffered pneumothorax with a persistent air leak after blunt chest

Accepted for publication Aug 3, 1992.

COLD = chronic obstructive lung disease; F = female; M = male; tetracycline = attempt at tetracycline pleurodesis without success.

trauma. Nine patients had to be treated because of a persistent air leak of operative or iatrogenic origin: 6 among them after lobectomy, bilobectomy, or segmentectomy, 1 after a spine operation, 1 after pleurocentesis, and 1 after subclavian vein puncture.

Thorax drainage had been instituted for a mean of 12 days, and 6 patients had previously been treated (in another hospital) without success with at least one attempt of tetracycline pleurodesis 7 to 15 days before quinacrine pleurodesis. All patients received the four planned quinacrine administrations. One patient, patient 18, needed six quinacrine injections for complete healing.

Episodes of major pain were not reported, and analgesics were not administered during or after the quinacrine injection. Fever developed in all but 3 patients but always disappeared within 48 hours after the last injection.

Patient 5 was in intensive care and on a ventilator because of a severe pneumonia superimposed on a chronic obstructive lung disease. While he was being ventilated an important (>8 L/min) and persistent (thorax drainage for 14 days and failure of tetracycline pleurodesis) air leak developed. He was successfully treated with quinacrine pleurodesis while still being ventilated.

Patient 11 had generalized emphysema and was treated in another hospital for right-sided pneumothorax. He underwent 3 weeks of drainage and one tetracycline pleurodesis. After removal of the drain, recurrence occurred and the patient was referred to our department. A new thoracostomy was performed, showing an air leak of about 2 L/min. The lung expanded and four quinacrine applications were given. The patient was discharged without problems but had to be hospitalized again 13 days later for a second recurrence. Thoracotomy was performed and basal fibrinous adhesions were found. The apical pneumothorax was treated with a pleurectomy. The patient did not tolerate the thoracotomy and died 13 days after the operation of respiratory failure.

Late recurrences, defined as a recurrence occurring after 1 month, were not observed over a mean follow-up period of 30.5 months (standard deviation, 29.0 months; range, 0.5 month to 89.0 months).

Quinacrine plasma concentrations were measured in 4 patients. In 2 of them, plasma concentrations were not detectable (<0.2 ng/mL). In the other 2 patients a very rapid uptake of quinacrine from the pleural space, with a peak concentration within 30 minutes, was seen. How-

ever, only very low quinacrine plasma concentrations were found (peak concentrations, 7.8 and 3.7 ng/mL; concentrations after 2 hours, 0.8 and 0.5 ng/mL).

Minimal air-fluid levels shown by radiography after pleurodesis in 3 patients disappeared spontaneously after 4 weeks.

Comment

Many substances have been used to obtain chemical pleurodesis: kaolin, silver nitrate, talc, cyanoacrylate, dicetylphosphate, olive oil, blood, camphor oil, tetracycline, 50% dextrose solution, and quinacrine [7, 8]. More recently, thoracoscopic application of fibrin glue has been proposed, with varying short-term and long-term recurrence rates (4.4% to 25%) [9-11].

Quinacrine hydrochloride, a semisynthetic alkaloid, was the first low-toxicity antimalarial [12]. It has been used for treatment of malignant pleural, pericardial, and peritoneal effusions [13]. The use of quinacrine for pneumothorax patients is recommended by Boat [14], Cattaneo [15], Kattwinkel [16], Jones [17], and their associates. Larrieu and colleagues [5] in 1978 published the first study comparing quinacrine pleurodesis with surgical pleurectomy (20 patients in the quinacrine pleurodesis group).

The present study confirms that intrapleural administration of quinacrine is a very effective treatment for complicated pneumothorax. There was only one treatment failure: 27 of 28 cases were successfully treated and among these cases, no recurrences occurred.

Intrapleural administration of quinacrine appears to be well tolerated by patients. Moderate to high fever was observed in most patients, probably caused by pleural inflammation rather than by systemic reactions. Indeed, serum levels of quinacrine in 4 patients remained undetectable or very low.

Although the present series is relatively small, the recurrence rate after quinacrine pleurodesis (1/28) tends to approximate the low recurrence rates of a surgical procedure.

It was beyond the scope of the current study to examine how these satisfactory results were obtained. In contrast to pleurodesis with tetracyclines or talc, quinacrine was repeatedly administered. It is very likely that these results do not only depend on the product itself, but also on the repeated administration of the drug. The observation in patient 18 that a residual pneumothorax after four quinacrine applications disappeared after two extra administrations further supports this contention.

Tetracycline and talc pleurodesis remain very painful even when adequate doses of sedation and analgesics are given [18]. The finding that the pain associated with quinacrine pleurodesis is of a much lesser degree represents a considerable advantage. Moreover, quinacrine was successful in 5 of the 6 patients with recurrence after tetracycline pleurodesis.

Several side effects of quinacrine used in a higher dose (400 mg daily or more) have been reported: fever, pain,

nausea, vomitus, ileus, hallucinations, hypotension, dyspnea, yellow skin pigmentation, headache, and convulsions [19, 20]. However, with the exception of fever and minor pain we did not see any of these early side effects. It has been suggested that the frequency and severity of complications are dose related [21]. To our knowledge, late complications never have been mentioned.

In conclusion, this study suggests that pleurodesis with repeated low doses of quinacrine represents a successful and almost painless treatment of recurrent pneumothorax or persistent air leak. Prospective trials with more patients should be designed to further evaluate this potential advantage and reassess the recurrence rate after quinacrine pleurodesis in spontaneous and idiopathic pneumothorax.

We are grateful to Prof Dr M. Bogaert for his support and advice.

INVITED COMMENTARY

This article is a useful reaffirmation of the effectiveness of this method of treatment of recurrent pneumothorax or pleural effusion and persistent air leak. Initially, a relatively high dose (greater than 500 mg) of intrapleural quinacrine hydrochloride was used in patients considered to be at high risk for open operation, and toxicity was substantial. However, after considerable experience with a lower dose regimen (100 mg of quinacrine intrapleurally daily for 4 days) we recommended this as the initial treatment of choice for patients with recurrent spontaneous pneumothorax. As with Janzing and associates, our patients usually experienced fever, 70% versus greater than 80% in the present report. Thirty percent of our patients did require mild analgesics versus essentially none of Janzing and associates' patients, but discomfort is modest at worst, far less than with even a limited thoracotomy and certainly less than with talc or tetracycline pleurodesis. We also had a low success rate with intrapleural instillation of tetracycline and with 50% glucose, and tetracycline for intrapleural use is no longer available in the United States. Although sterile vials of parenteral quinacrine hydrochloride are also no longer commercially available, instructions for preparation by hospital pharmacies are included in our referenced 1979 article.

To summarize the reported experience with the four daily dose regimen, quinacrine pleurodesis is effective in 95% of cases. On actuarial analysis, it is as effective on early and late (4 years) follow-up as scarification or pleurectomy, yet is associated with significantly fewer complications than operation (5% versus approximately 40%) and a 30% shorter average length of stay. Although average length of stay with tube thoracostomy alone is an additional 30% shorter, a recurrence rate of more than 20% within 1 year confirms the ineffectiveness of this approach in cases of recurrent pneumothorax.

A concern is that quinacrine pleurodesis may be too good. How formidable will the worst-case adhesions be in

a patient with cystic fibrosis subsequently coming to transplantation? In a report of postmortem findings after this treatment, discussed in our article, both pleural spaces were completely adhered. Of the 21 patients with pneumothoraces who we treated between 1971 and 1977, 1 patient suffered a small ipsilateral recurrence 2 years after quinacrine instillation. Although this patient did come to operation at another institution, relatively dense adhesions were encountered, indicating that operation was almost certainly not needed. Further, the patient required reoperation for bleeding. Can a treatment be too effective? Although Janzing and associates have in 1 case extended the number of instillations required in a resistant case to six (a measure of the low toxicity and discomfort associated with the method) possibly the majority of patients only need two or three instillations localized at the apex. A prospective clinical or laboratory trial of various doses and positions versus operation could be of considerable interest.

In the meantime, I support Janzing and associates' recommendation that intrapleural instillation of quinacrine for treatment of recurrent spontaneous pneumothorax appears to be the treatment of choice. With worldwide increasing concerns about patients' safety and medical care costs, this treatment is less invasive even than the thoracoscopic approaches described more recently and is less expensive in both the short and long term than any other approach.

Secondary Spontaneous Pneumothorax

Fumihiko Tanaka, MD, Masatoshi Itoh, MD, Hiroshi Esaki, MD, Jun Isobe, MD, Youichiro Ueno, MD, and Ritsuko Inoue, MD

Department of Thoracic and Cardiovascular Surgery, National Gifu Hospital, Gifu, Japan

To assess the clinical manifestations and therapy of secondary spontaneous pneumothorax (SSP), 123 episodes of SSP in 67 patients were retrospectively reviewed and were compared with 254 episodes of primary spontaneous pneumothorax in 130 patients. The major underlying lung diseases associated with SSP were emphysema (22 patients) and tuberculosis (21 patients). The average age of patients with SSP was 66.8 years, and the most common symptom was dyspnea. The average arterial oxygen tension at onset of SSP was 61.1 ± 12.1 mm Hg (mean $\pm$ standard deviation), which was lower than that of patients with primary spontaneous

pneumothorax ($p < 0.01$). The recurrence rate of open thoracotomy with pleural abrasion was 12.5% (3 of 24 episodes), which was not lower than that of thoracostomy tube drainage with chemical pleurodesis using tetracycline (recurrence rate, 18.8%) ($p > 0.5$). We concluded that considering the high age of the patients, the presence of underlying lung diseases, and the increased operative risk, thoracostomy tube drainage rather than open thoracotomy was preferred as the first choice of therapy for SSP.

(*Ann Thorac Surg* 1993;55:372-6)

Spontaneous pneumothorax is classified into primary and secondary spontaneous pneumothorax. Primary spontaneous pneumothorax (PSP) occurs in healthy individuals without a coexisting lung disease, usually as a result of rupture of a pulmonary bleb. Secondary spontaneous pneumothorax (SSP) is a pneumothorax that is related to the presence of an underlying lung disease such as chronic obstructive lung disease or pulmonary tuberculosis [1]. The clinical manifestations and treatment of PSP are well-documented and established, and there is minimal morbidity and no mortality when properly treated. However, in SSP, which often occurs in older individuals, the morbidity and mortality rates may be substantial, regardless of adequate therapy [2]. The purpose of this report is to describe the clinical manifestation of SSP and also to assess the management, especially by open thoracotomy, of SSP.

Material and Methods

A total of 197 patients with 377 separate episodes of spontaneous pneumothorax treated at National Gifu Hospital from January 1, 1984, to December 31, 1988, were reviewed for this study. Pneumothoraces secondary to trauma or iatrogenic causes were excluded. Among these episodes of spontaneous pneumothorax, 123 episodes (32.5%) in 67 patients (34.0%) were related to the presence of obvious coexisting lung diseases and were categorized as SSP.

All medical records of patients with spontaneous pneumothorax were reviewed, and those of patients with SSP were compared with those of patients with PSP. Follow-up was accomplished by review of outpatient records

or by telephone interview, and the minimum length of follow-up was 2 years. The average length of follow-up in SSP was 4.1 years, and that in PSP was 4.3 years. Counts were compared with the use of χ^2 analysis. Continuous data were compared by Student's *t* test if they were approximately normally distributed, or by a Mann-Whitney U test if not.

Results

Underlying Diseases

The most common underlying disease was pulmonary emphysema, and 45 episodes (36.6%) in 22 patients (32.8%) occurred with this disease (Table 1). Twenty-eight episodes (22.8%) in 21 patients (31.3%) occurred with pulmonary tuberculosis. Pneumoconiosis was a cause of 26 episodes (21.1%) of spontaneous pneumothorax in 9 patients (13.4%). Less commonly, pneumothoraces occurred secondary to pulmonary fibrosis (9 episodes in 5 patients), primary lung cancer (4 episodes in 4 patients), sarcoidosis (2 episodes in 2 patients), or bronchial asthma (4 episodes in 2 patients). Pneumonia, diffuse panbronchiolitis, and eosinophilic granuloma were a cause of pneumothorax in 1 patient each.

Sex and Age

Sixty-one patients with SSP were male, and 6 were female (Table 2). The average age at the diagnosis of SSP was 66.8 years (range, 12 to 85 years), and was significantly greater than that of patients with PSP ($p < 0.01$).

Clinical Manifestations

The most common symptom of SSP was dyspnea, which occurred in 79 episodes (64.2%), whereas patients complained of dyspnea in only 26 episodes of PSP (10.2%) ($p < 0.01$) (see Table 2). Chest pain, the most common

Pneumonia	1 (0)	1
Diffuse panbronchiolitis	1 (0)	1
Eosinophilic granuloma	1 (0)	3
Total	67 (6)	123

symptom in PSP, was complained of in only 49 episodes of SSP (39.8%). Four patients with SSP were asymptomatic, with diagnosis made on a routine roentgenogram, whereas only 1 patient with PSP was asymptomatic, but the difference was not statistically significant ($0.05 < p < 0.1$).

Arterial oxygen tension at the onset of SSP was 61.1 ± 12.2 mm Hg (mean $\pm$ standard deviation), which was significantly less than the arterial oxygen tension at onset of PSP ($p < 0.01$). Arterial oxygen tension after resolution of SSP was 76.5 ± 13.0 mm Hg, which was also less than the arterial oxygen tension after resolution of PSP ($p < 0.01$).

Nonoperative Therapy

Ninety-nine of 123 episodes of SSP (80.5%) were treated with nonoperative procedures, whereas 154 of 254 episodes of PSP (60.6%) were treated with nonoperative procedures (Table 3). This difference is statistically significant ($p < 0.01$). Nonoperative procedures included bed-

rest and observation in 10 episodes, needle aspiration in 11 episodes, and thoracostomy tube drainage in 78 episodes. In 32 of 78 episodes treated with tube drainage, chemical pleurodesis using tetracycline was performed.

Operation and Indications

Only 24 episodes of SSP (19.5%) were treated with open thoracotomy, whereas 100 episodes of PSP (39.5%) were treated with open thoracotomy ($p < 0.01$) (see Table 3). The most common indication for open thoracotomy of SSP was a persistent air leak, which accounted for 15 of 24 episodes of SSP (62.5%), whereas only 22 of 100 episodes of PSP (22.0%) were treated with open thoracotomy due to a persistent air leak ($p < 0.01$). The other indications in SSP were recurrent episodes (4 episodes), large blebs or bullae (4 episodes), and bilateral pneumothorax (1 episode). On the other hand, the most common indication of open thoracotomy for PSP was recurrent episodes (58 of 100 episodes).

A transaxillary approach was used in open thoracotomy for both SSP and PSP. Total excision of blebs and bullae and oversewing of the area were performed in 22 patients with SSP and in all 100 patients with PSP. Right pneumonectomy of the destroyed lung was performed in 1 patient and right upper lobectomy was performed in the other patient with SSP. Pleural abrasion with a dry gauze was also performed in all but 1 patient with SSP. Parietal pleurectomy was not performed in any of the patients with SSP. Pleural abrasion was performed in all patients with PSP.

Recurrence

Recurrence occurred in 38 of 123 episodes of SSP (30.9%) (Table 4). The recurrence rate with open thoracotomy was 12.5%, which was less than that with nonoperative therapy (35.4%) ($0.02 < p < 0.05$). The recurrence rate with thoracotomy tube drainage with chemical pleurodesis was only 18.8%, which was comparable with that with open thoracotomy ($p > 0.5$).

Table 4. Recurrence Rates of Various Treatments in Patients With Secondary and Primary Spontaneous Pneumothorax

Treatment	SSP	PSP	p Value
Nonoperative therapy	35.4% (35/99) ^a	44.8% (69/154)	NS
Observation	20.0% (2/10)	52.5% (31/59)	<0.05
Needle aspiration	45.5% (5/11) ^a	58.3% (7/12)	NS
Tube drainage	35.9% (28/78) ^a	37.3% (31/83)	NS
Without pleurodesis	47.8% (22/46) ^a	38.2% (31/81)	NS
With pleurodesis	18.8% (6/32) ^b	0.0% (0/2)	NS
Open thoracotomy	12.5% (3/24)	3.0% (3/100)	<0.01
Total	30.9% (38/123)	28.3% (72/254)	NS

^a Significance: $p < 0.05$, nonoperative therapy versus open thoracotomy in secondary spontaneous pneumothorax. ^b Significance: $p < 0.05$, tube drainage with pleurodesis versus without pleurodesis in secondary spontaneous pneumothorax.

NS = not significant; PSP = primary spontaneous pneumothorax; SSP = secondary spontaneous pneumothorax.

The overall recurrence rate in patients with PSP was 28.3% (72 of 254 episodes), which was comparable with that in patients with SSP (30.9%). Only 3 of 100 patients with PSP (3.0%) treated with open thoracotomy had a recurrence, whereas 3 of 24 patients with SSP (12.5%) treated with open thoracotomy had a recurrence ($0.02 < p < 0.05$).

Eleven of 38 recurrences in SSP (28.9%) occurred within 1 month or less, 16 recurrences (42.1%) in 1 to 6 months, one recurrence (2.6%) in 6 to 12 months, and four recurrences in 1 to 2 years (Fig 1). Thus, 32 recurrences in SSP (84.2%) occurred within 2 years of the previous episode. The average time to recurrence in SSP was 280.0 ± 77 days ($\pm$ standard error), which was similar to that in PSP (338.1 ± 55.7 days).

Complications

There were no complications related to nonoperative therapy for both SSP and PSP. No intraoperative complications occurred. There were 9 postoperative complications in SSP: 7 air leaks that persisted more than 5 days, 1

pneumonia, and 1 heart failure (Table 5). The average postoperative chest tube placement interval in SSP was 4.3 ± 2.3 days ($\pm$ standard error), which was significantly longer than that in PSP ($p < 0.01$).

Mortality

Twelve patients with SSP died (Table 6), whereas no patients with PSP died. One patient (patient 7) who had open thoracotomy and in whom an air leak persisted postoperatively died of pneumonia 10 days after operation. Six patients (patients 1, 2, 3, 4, 5, and 6) died before the pneumothorax had resolved. All of these 6 patients died within 1 month after the onset of the pneumothorax. Five patients (patients 8, 9, 10, 11, and 12) died after pneumothorax had resolved; 4 of these patients died within 2 months after the pneumothorax had resolved. Patient 12 with pulmonary tuberculosis died 9 months after the pneumothorax had resolved, due to development of lung cancer.

Comment

Spontaneous pneumothorax commonly occurs in young male patients without any apparent lung disease; it occurs less commonly in patients with underlying lung disease, which is categorized as secondary [1, 3]. The most common underlying lung disease in our series was, as has

Fig 1. Interval between resolution of pneumothorax and recurrence.

Table 5. Postoperative Complications

Complications	SSP	PSP	p Value

2	68	Male	Lung cancer	Radiation pneumonitis	2 days
3	83	Male	Tuberculosis	Tuberculosis	9 days
4	64	Male	Tuberculosis	Pneumonia	10 days
5	84	Male	Pneumonia	Pneumonia	10 days
6	48	Male	Pulmonary fibrosis	Respiratory failure	21 days
7	71	Male	Emphysema	Operation-related death	20 days
Patients who died after pneumothorax was resolved					
8	70	Male	Emphysema	Pneumonia	7 days
9	70	Female	Lung cancer	Lung cancer	2 years
10	58	Male	Tuberculosis	Tuberculosis	50 days
11	84	Male	Emphysema	Pneumonia	21 days
12	81	Male	Tuberculosis	Lung cancer	9 months

already been reported [1, 2], pulmonary emphysema, accounting for 36.6% of cases of SSP. Pulmonary tuberculosis accounted for 22.8% in our series, whereas Getz and Beasley [4] reported that only 3 (10.7%) of 28 secondary pneumothoraces were related to pulmonary tuberculosis [4]. This may suggest that in our country, Japan, the prevalence of tuberculosis remains high.

The most common symptom in patients with SSP was not chest pain, which was the most common symptom in patients with PSP, but was dyspnea; in patients with SSP, who are usually older than those with PSP and also have previously diminished lung function because of underlying lung diseases, even a small pneumothorax can produce severe respiratory distress [5].

Management and Recurrence

Spontaneous pneumothorax may be treated with observation, needle aspiration, thoracostomy tube drainage with or without pleurodesis, or open thoracotomy. The choice of therapy must be based on the severity and duration of symptoms, the presence of an underlying pulmonary disease, a history of previous episodes, and the occupation of the patient. In management of our patients with SSP, tube drainage was performed in 78 episodes (63.4%), and observation and needle aspiration were performed in only 10 episodes (8.1%) and 11 episodes (8.9%), respectively. Shields and Oilschlager [2] reported that observation was carried out in only 7 episodes (11.7%), needle aspiration in only 4 episodes (6.7%), and thoracostomy tube drainage in 39 episodes (65.0%) in a series of 49 men 40 years of age and older with 60 episodes of spontaneous pneumothorax. Patients with SSP should be treated with tube drainage regardless of the size of pneumothorax for rapid reexpansion of functioning lung tissue, whereas bed-rest or needle aspiration has been reevaluated in selected healthy young patients with a small pneumothorax [1, 2, 5]. In these patients, air leaks sometimes last more than 10 days, but because of a significantly increased operative risk, tube

drainage should be continued for a longer period than in PSP.

The risk of recurrent pneumothorax varies widely in published reports because of the varying age and associated lung disease patterns of the patients. DeVries and Wolfe [6] estimated that there was a 32% recurrence rate among patients treated with nonoperative methods. Granke and co-workers [7] reported that 11 of 49 patients treated with tube drainage had a recurrence (22.4%), and there were no recurrences in the operative group of 78 patients. Seremetis [8] reported a 49% rate (21 of 44) of recurrence in patients treated with bed-rest, a 38% recurrence rate (31 of 81) in those treated with tube drainage, and no recurrence after open thoracotomy. Schoenenberger and co-workers [9] reported that recurrence rates were 30% after 10 ± 10 months in both PSP and SSP. Thus, the recurrence rates observed in our series of 30.9% in SSP and 28.3% in PSP are comparable with figures seen in other series.

To prevent recurrence, the diseased site should be resected and the pleural space obliterated. Pleural space obliteration is accomplished by chemical pleurodesis, mechanical pleural abrasion, or partial pleurectomy. Chemical pleurodesis is a blind procedure and can result in adhesions that are too dense and in scars over some pleural areas, with inadequate adhesions in other areas; this can result in serious pleural complications. In spite of these disadvantages, chemical pleurodesis finds occasional application in the prevention of recurrence in patients with serious respiratory impairment due to underlying lung disease in whom thoracotomy for pleurectomy or pleural abrasion would carry an unacceptable risk. Thoracostomy tube drainage with chemical pleurodesis using tetracycline was used in 32 of our episodes of SSP. The recurrence rate was 18.8%, which is significantly less than that of observation alone, needle aspiration, or tube thoracotomy without pleurodesis, and was comparable with that of open thoracotomy with pleural abrasion. Many surgeons continue to consider bleb resection

and dry gauze pleural abrasion, which was employed in our series, to be effective in preventing recurrence [10]. Youmans and co-workers [11] reported their clinical experience with pleural abrasion (only one recurrence in 30 patients). But our result (recurrence rate with pleural abrasion, 12.5%) suggests that pleural abrasion is not adequate to prevent recurrence in SSP.

Weeden and Smith [12] reported their results of pleurectomy and demonstrated only a 3.7% major complication rate (8/241). The recurrence rate was only 0.43% (one in 233 patients) [12], which may be lower than the recurrence rate (12.5%) in our series treated with pleural abrasion. Deslauriers and co-workers [13] reported that only 2 (0.6%) of 409 patients treated with pleurectomy had a recurrence. Moreover, Weeden and Smith [12] reported no significant change in the results of respiratory function tests performed before and 6 months or more after pleurectomy. Thus, they advocated the use of transaxillary apical pleurectomy for the younger age group, and a full pleurectomy in the older age group, who often have chronic obstructive lung disease that is not confined to the apex of the upper lobe.

Morbidity and Mortality

Even though most patients with SSP can be managed successfully, death may result from respiratory failure caused by the pneumothorax, particularly in older patients with extensive underlying lung disease. Shields and Oilschlager [2] reported a 16.3% mortality rate (8 of 48 patients) in patients more than 40 years old. Six of these eight deaths were contributed to or were directly the result of the pneumothorax. Dines and co-workers [14] reported 10 of 57 patients with SSP associated with emphysema who died as a result of spontaneous pneumothorax, and concluded that although an uncommon complication, spontaneous pneumothorax is most serious and requires emergency thoracostomy tube drainage.

Continuous Intercostal Nerve Block Versus Epidural Morphine for Postthoracotomy Analgesia

Jonathan Richardson, FCAnaes, Sabaratnam Sabanathan, FRCS, Jibah Eng, FRCS, Alan J. Mearns, FRCS, Christina Rogers, FCAnaes(I), Carolyn S. Evans, FCAnaes, Jane Bembridge, FCAnaes, and Mohammed R. Majid, MBBS

Departments of Anaesthetics and Thoracic Surgery, Bradford Royal Infirmary, Bradford, England

Twenty patients undergoing elective thoracotomy were randomized into two groups, receiving either lumbar epidural morphine (n = 10) or continuous extrapleural intercostal nerve block (n = 10). Subjective pain relief was assessed on a linear visual analogue scale. Pulmonary function (peak expiratory flow rate, forced expiratory volume in 1 second, and forced vital capacity) was measured on the day before operation and daily for 4 days after operation. Pulse oximetry monitoring was used to determine the incidence of hypoxemia. No significant difference was observed between the groups concerning pain relief (except at 28 hours, in favor of the

intercostal nerve block group), respiratory performance, or arterial oxygen saturation. Vomiting, pruritus, and urinary retention occurred only in the epidural group, whereas nausea occurred significantly less frequently in the extrapleural group. We conclude that after thoracotomy continuous extrapleural intercostal nerve block is as effective as lumbar epidural morphine in reducing postoperative pain and restoring pulmonary mechanics. Because of the significantly lower complication rates we favor continuous extrapleural intercostal nerve block for postthoracotomy analgesia.

(*Ann Thorac Surg* 1993;55:377-80)

Thoracotomy causes severe postoperative pain and marked impairment of pulmonary functions [1]. Conventional analgesia using opiates has been shown to be inadequate [2] and may contribute to further deterioration of pulmonary mechanics by impairing the natural sigh mechanism [3]. Epidural analgesia using local anesthetic agents provides effective postthoracotomy analgesia but is associated with a high incidence of complications including hypotension from bilateral sympathetic blockade [4]. Epidural opiates are widely used to provide postthoracotomy pain relief [5, 6] but may be associated with a high incidence of complications including nausea and vomiting, urinary retention, pruritus, and delayed respiratory depression, which is unpredictable and insidious in onset [7].

We have previously shown that continuous extrapleural intercostal nerve block provided effective analgesia after thoracotomy and aided postoperative recovery of pulmonary functions [8, 9]. Its use for up to 5 days has not been associated with any significant complications. We believe that continuous extrapleural intercostal nerve block may provide as good an analgesia as epidural analgesia without the associated complications. This study was designed to prove this by comparing lumbar epidural morphine with continuous extrapleural intercos-

tal nerve block with bupivacaine after elective thoracotomy.

Patients and Methods

Patient Selection

This study was approved by the hospital's ethics committee. Written informed consent was obtained from 20 adults undergoing elective thoracotomy for pulmonary and esophageal procedures. Exclusion criteria included marked obesity, known sensitivity to morphine or bupivacaine, substantial preoperative analgesic consumption, and standard contraindications to epidural catheter insertion.

Perioperative Period

Patients were given preoperative instructions on the use of a hand-held spirometer (Respiradyne; Chesbrough-Pond's Ltd, Greenwich, UK) and the linear visual analogue scale consisting of a 10-cm graduated line with 0 indicating no pain and 10 indicating the worst pain imaginable. Patients were premedicated with temazepam. Upon arrival in the anesthetic room patients were randomized to receive either epidural morphine (group A) or extrapleural bupivacaine (group B).

Before the induction of anesthesia patients in group A had an epidural catheter inserted into the lumbar epidural space at the L2-3 interspace. The epidural placement of the catheter and the lack of spinal block were confirmed by a 4-mL test dose of 1% plain lignocaine. General

anesthesia was induced with thiopentone, and a competitive muscle relaxant was used to aid tracheal intubation with a double-lumen endobronchial tube. Anesthesia was maintained with 50% nitrous oxide in oxygen and a delivered concentration of 0.5% to 2% isoflurane. Intraoperative systemic opiates were avoided in both groups.

Patients in group B received general anesthesia as described. Before closure of the chest, the parietal pleura overlying the paravertebral space was lifted. The paravertebral space was then entered using Lahey forceps. The catheter was inserted via a 16-gauge disposable Touhy (Portex Ltd, Hythe, UK) needle. The tip of the catheter was inserted into the paravertebral space for a distance of 3 to 4 cm. The parietal pleura was then loosely reattached, as previously described [8].

Approximately 60 minutes before the end of the operation patients in group A received a bolus of morphine in preservative-free normal saline solution epidurally (Table 1), and patients in group B received a bolus of 20 mL of 0.5% bupivacaine through the extrapleural catheter before the end of the operation.

All patients were extubated at the end of the operation. In the recovery room both groups were given oxygen at 4 L/min by face mask. This was continued for 24 hours. No further oxygen was given unless oxygen saturations fell below 90%. Group A received an infusion of 50 µg/mL morphine in normal saline solution through the epidural catheter at a rate of 100 µg/h, based on previously described technique [9]. Group B patients had an infusion of bupivacaine at a dose of 0.5 mg · kg⁻¹ · h⁻¹ with a concentration of 5 mg/mL through the extrapleural catheter. In addition, patients had access to intramuscular omnopon and rectal diclofenac as requested. No attempt was made to withhold requested analgesia. Personnel taking measurements and personnel setting up the infusion were kept "blind."

Monitoring

Postoperative monitoring was carried out as recommended by Ready and associates [5] and consisted of hourly respiratory rates and sedation levels for 24 hours, dropping to every 4 hours thereafter. Temperature, pulse rate, and blood pressures were measured every 4 hours.

Postoperative pain was assessed by the patients themselves on the visual analogue scale. Pain scores were recorded at 4-hour intervals for a total of 4 days. Nausea, vomiting, pruritus, urinary retention, and the use of additional analgesics were recorded. Twenty-four-hour continuous pulse oximetry was also recorded.

Respiratory function tests (peak expiratory flow rate, forced expiratory volume in 1 second, and forced vital capacity) were performed preoperatively and daily postoperatively in the sitting position using a Respiradyne after 5 mg of nebulized salbutamol. The best of three measurements was recorded. Results were expressed as a percentage of preoperative values.

Statistics

The results were analyzed using the Kruskal-Wallis one-way analysis of variance by ranks and the Mann-Whitney U test to determine statistical significance.

Results

The groups were comparable with respect to age, smoking habits, body habitus, and surgical procedures (Table 2).

Pain Relief

Both techniques provided good analgesia as demonstrated by low pain scores. There was no significant difference between the groups, except at 28 hours when continuous extrapleural intercostal nerve block provided significantly better analgesia. No significant difference was observed in the use of rectal diclofenac (6 patients in group A, 8 in group B). One patient in each group required one opiate supplementation, whereas 3 patients in group B required opiate injection twice.

Postoperative Pulmonary Function

The mean values of peak expiratory flow rate, forced expiratory volume in 1 second, and forced vital capacity as a percentage of preoperative control values were maximally reduced at 24 hours in both groups. There was no statistically significant difference between the two groups.

Pulse Oximetry

There was no significant difference in the arterial oxygen saturation between the two groups.

Complications

Table 3 shows the complications associated with each method of analgesia. There were significantly ($p < 0.05$) higher incidences of vomiting requiring antiemetic treatment, pruritus, and urinary retention requiring urinary

catheterization in the epidural group. More patients who received epidural morphine complained of nausea than those in the extrapleural group, but this was not statistically significant. No periods of excessive somnolence or a respiratory rate of less than 8 per minute were detected in any patient. One elderly patient in group B had an episode of confusion that responded to a 6-hour cessation of infusion.

Comment

The unilateral nature of most thoracic surgical procedures makes intercostal nerve blocks feasible. We have recently demonstrated that the site of action of continuous extrapleural intercostal nerve block is in the paravertebral space [10]. The paravertebral space is the ideal site not only because the intercostal nerves are in small bundles without fascial sheath but also because local anesthetic agents here effectively block the posterior primary rami and the ipsilateral sympathetic chain [11]. Blocking the posterior primary rami after thoracotomy relieves backache caused by straining of vertebral muscles and ligaments of the costovertebral and costotransverse ligaments. Unilateral sympathetic block may have a useful effect on the endocrine-metabolic response to operation without the hypotension associated with bilateral sympathetic block from epidural block [12]. We previously demonstrated in a randomized, double-blind control study that continuous extrapleural intercostal nerve block using bupivacaine is efficacious in producing postthoracotomy analgesia and in aiding postoperative recovery of pulmonary mechanics, thus preventing postoperative pulmonary complications [8]. Measurements of bupivacaine levels have not demonstrated toxic levels being achieved (Berrisford RG, Sabanathan S, Mearns AJ; unpublished results), and bupivacaine toxicity did not develop in any patient after 5 days of infusion.

After thoracotomy, epidural opiate is effective whether infused by the lumbar or the thoracic routes [13]. There is evidence that the quality of analgesia from opiates is no different whatever routes they are given [14]. Centrally administered opiates are effective in smaller doses. The rostral spread of opiates, however, may result in delayed respiratory depression, which may be unpredictable. This has been described in up to 13.5% of patients [7], although large-scale studies have quoted rates of 0.25% to 0.9% [15, 16]. We did not detect any patients with this complication in this series. The high incidence of the other

complications of epidural morphine, including urinary retention, nausea, vomiting, and pruritus, have been previously observed [15]. These potential complications, which may be life-threatening in the case of delayed respiratory depression, mean that diligent observations and intensive nursing care are mandatory.

The placement of the paravertebral catheter at thoracotomy can be achieved under direct vision expeditiously. With experience, epidural catheterization can be performed without much delay, although failure of cannula insertion has been described in up to 10.9% of patients [17]. With minimal modification in technique, the paravertebral block can also be effectively applied after parietal pleurectomy [18].

We have demonstrated in this study that continuous extrapleural intercostal nerve block provided as good an analgesia as epidural morphine and has similar beneficial effects on postoperative pulmonary functions. The lack of complications with continuous intercostal nerve block, with an understanding of its mechanism of action, means that this method is a safe and effective analgesia after thoracotomy. We believe it should be more widely used in view of its simplicity and safety.

INVITED COMMENTARY

In this study Richardson and associates compare treatment of postthoracotomy pain by continuous infusion of morphine into the lumbar epidural space versus their previously described technique of infusing local anesthetic into the extrapleural paravertebral space. The extrapleural technique is somewhat similar to the method of intrapleural anesthetic administration that has recently enjoyed popularity. Theoretically, the extrapleural technique may offer advantages over intrapleural administration of local anesthetics. Because the local anesthetic is deposited closer to the intercostal nerves, without needing to diffuse across the parietal pleura, the analgesic efficacy may be greater. In addition, analgesia is probably less dependent on patient positioning, and the chest tubes do not need to be clamped to prevent the local anesthetic from being removed.

Although Richardson and associates found comparable analgesia with fewer side effects using their extrapleural technique, the reader needs to be aware that the epidural morphine regimen used for comparison may not be the optimal implementation of that technique. They relied on relatively low doses of epidural morphine administered in a small volume (2 mL/h) through a lumbar catheter far removed from the level of the thoracotomy. Although lumbar epidural opioid administration can be used effectively to treat postthoracotomy pain, larger doses or volumes of solution are necessary as compared with administration in the thoracic region. Indeed, the study

Richardson and associates cite as the basis for their epidural opioid technique [9] used thoracic catheters and doses of morphine 3 to 6 times greater than those used in the current study.

The reader should also be aware that the bupivacaine infusion used for extrapleural analgesia represents more than twice the maximum recommended dose for a 24-hour period (400 mg). Although Richardson and associates state that they did not see any complications or side effects in their extrapleural group, it seems likely to us that the confusion experienced by one of their patients may have been due to bupivacaine toxicity. This is supported by their statement that the confusion resolved by stopping the infusion for 6 hours.

In summary, we applaud Richardson and associates for developing an effective alternative method for providing postthoracotomy analgesia. However, we believe that the safety and superiority of their method over existing techniques still needs to be confirmed in a larger series of patients.

Continuous Intercostal Analgesia With 0.5% Bupivacaine After Thoracotomy: A Randomized Study

Michel Deneuville, MD, Anne Bissier, PT, Jean François Regnard, MD, Martine Chevalier, PT, Philippe Levasseur, MD, and Philippe Hervé, MD

Service de Chirurgie Thoracique, Département de Kinesithérapie, et Laboratoire d'Explorations Fonctionnelles Respiratoires, Centre Chirurgical Marie Lannelongue, Université Paris-Sud, Le Plessis Robinson, France

This study was undertaken to evaluate the effectiveness of 0.5% bupivacaine (360 mg/day) as a continuous infusion through an indwelling intercostal catheter inserted intraoperatively in the management of pain after thoracotomy. Eighty-six patients were randomized into three groups: group 1 = intercostal bupivacaine, group 2 = intercostal saline solution, and group 3 = fixed-schedule intramuscular buprenorphine. Supplementary buprenorphine was given as required. Pain and pulmonary function were assessed throughout the first 5 days after operation. Pain score was lower in group 1 than in group 2 for the first 8 hours after operation ($p < 0.02$). During the first 3 postoperative days, mean postoperative pain

scores of 5 or more were recorded in 9% of group 1 patients versus 40% of group 2 patients ($p < 0.05$) and 13% of group 3 patients (not significant). Total doses of buprenorphine were lower in groups 1 and 2 than in group 3 ($p < 0.001$). No between-group differences in pulmonary function were observed. Respiratory complications occurred in no patients in groups 1 and 3 versus 5 in group 2 ($p < 0.05$). Continuous intercostal bupivacaine provided similar early pain control as compared with fixed-schedule narcotics but induced better analgesia with fewer complications than on-demand narcotics alone (group 2).

(*Ann Thorac Surg* 1993;55:381-5)

Narcotics are effective in controlling postoperative pain but are associated with respiratory depression and suppression of the cough reflex. This has led to a persistent search for methods of pain relief that do not contribute per se to depressed pulmonary function. Intercostal nerve blockade using intermittent injections of 0.5% bupivacaine hydrochloride has been proved effective in providing pain relief after abdominal and thoracic operations [1, 2]. Continuous intercostal analgesia with an infusion of 0.5% bupivacaine hydrochloride through an indwelling catheter placed extrapleurally during thoracotomy has therefore been proposed [3] as a means for maintaining analgesia over a prolonged period after thoracotomy. In an attempt to evaluate the effectiveness of continuous intercostal analgesia with 0.5% bupivacaine without epinephrine as compared with fixed-schedule or on-demand intramuscular narcotics, we conducted the following randomized, prospective study in 86 patients after thoracotomy.

Material and Methods

After obtaining the approval of the Paris-Sud University Human Investigation Committee as well as written informed consent from our patients, 86 patients (61 men and 24 women) undergoing lobectomy or wedge resection

through a posterolateral thoracotomy in the fifth intercostal space were studied from September 1989 to January 1991. Patients with abnormal preoperative pulmonary function tests or a history of allergy to local anesthetics were excluded.

The patients were randomized into three experimental groups: group 1 = continuous intercostal 0.5% bupivacaine hydrochloride without epinephrine ($n = 26$), group 2 = continuous intercostal 0.9% saline solution ($n = 26$), and group 3 = intramuscular buprenorphine sulfate, 0.3 mg three times daily ($n = 34$).

Technique

Before closure of the thoracotomy, a multiperforated epidural catheter (Perifix; Laboratoires Bruneau, Paris, France) was inserted percutaneously through a 16-gauge needle into the chest cavity through the anterior part of the fifth intercostal space. The needle was removed, and after slight peeling of the parietal pleura, the tip of the catheter was introduced into the extrapleural space and advanced under direct visual guidance from the neck of the fifth rib to the neck of the second rib. The catheter was positioned 3 to 4 cm from the spine. The parietal pleura was then stitched and the catheter was firmly secured to the skin. To ensure that there was no intrapleural leakage, 10 mL of 0.9% saline solution was injected through the catheter. Two chest tubes were placed anteriorly and posteriorly, and the chest was closed. These chest tubes were connected to water sealed drainage with 20 cm H₂O suction and were removed on the fifth postoperative day.

Accepted for publication Aug 26, 1992.

Address reprint requests to Dr Hervé, Laboratoire d'Explorations Fonctionnelles Respiratoires, Centre Chirurgical Marie Lannelongue, 133 Avenue de la Résistance, Le Plessis Robinson, 92350 France.

Identically appearing vials of 20 mL of 5% bupivacaine chlorhydrate or 20 mL of 0.9% saline solution were supplied by the Laboratoire Roger Bellon, Neuilly sur Seine, France. Each patient was allocated to one trial solution, identified by a number. At the conclusion of the operative procedure, 20 mL of the assigned solution was injected into the extrapleural space through the catheter. The intercostal catheter was connected through a bacterial Millipore filter to an infusion pump, and 3 mL/h of the solution was continuously infused for the first 5 postoperative days. The catheter was removed on the fifth postoperative day.

Study Protocol

The daily dose of bupivacaine (group 1) was 360 mg. In group 3 patients, 0.3 mg of intramuscular buprenorphine sulfate was given every 8 hours for the first 5 postoperative days. In each experimental group, the standard dose of rescue on-demand narcotic (intramuscular buprenorphine sulfate, 0.3 mg) was administered whenever any of the patients complained of pain.

During the study period, the patients assessed pain severity every 4 hours using the visual pain analog scale of El-Baz and associates [4] (0 = no pain; 10 = most severe pain imaginable). This visual pain analog scale shows five facial expressions for different degrees of pain positioned near the appropriate score on the scale.

Pulmonary function tests were performed by the physical therapist with the patient seated on the day before operation and on days 1, 3, 5, and 10 after operation; vital capacity and forced expiratory volume in 1 second were measured with a dry spirometer (Autospiro AS-600; Minato Medical Science Co, Osaka, Japan). Maximal static inspiratory and expiratory pressures at the mouth were measured according to the method of Black and Hyatt [5].

Heart rate, systolic and diastolic blood pressures, and temperature were monitored throughout the study. A chest roentgenogram was taken every day. Any complications and unusual events were recorded.

Analysis

The three therapeutic regimens to be compared were intercostal blockade with bupivacaine and on-demand narcotics (group 1), intercostal saline solution (placebo) and on-demand narcotics (group 2), and fixed-schedule narcotics and on-demand narcotics (group 3). Analysis of variance and χ^2 analysis were used to compare the three groups with regard to age, height, weight, sex, diagnosis, preoperative pulmonary function, length of procedure, and type of lung resection (wedge resection or lobectomy). For pain scores analysis, scores were averaged for each day and analyses were performed for the following blocks of time: first 8 hours postoperatively, first, second, third, and fourth postoperative days, and morning of the fifth postoperative day. To look for significant differences among treatment groups or over time in pain scores and pulmonary function tests, a multivariate analysis of variance with the Sheffé procedure for multiple comparisons was used. To compare percentages of patients with severe pain (mean pain score of 5 or more from postoperative

Table 1. Patient Characteristics^a

Operation performed			
Single lobectomy (%)	85	90	88
Wedge resection (%)	15	10	12

^a Where applicable, values are shown as mean ± standard error of the mean.

day 0 to 3) in the three groups, χ^2 analysis was used. Side effects and complications in the three groups were compared by χ^2 analysis. Analysis of variance was used to compare treatment groups with respect to supplemental narcotic use. A *p* value less than 0.05 was regarded as the threshold for statistical significance. Results are given as mean ± standard error of the mean.

Results

The patients in the three groups were similar with regard to age, weight, height, sex, diagnosis, duration of operation, and pulmonary function tests (Table 1).

Among the 86 patients, 76 completed the study. Three patients in group 1 and 3 patients in group 2 were excluded (malposition of the catheter in 3 patients and plugging of the lumen in 3 patients). Five patients in group 3 were excluded because they did not complete the visual pain analog scale during the entire study period.

Figure 1 shows the mean pain scores measured using the pain score analog scale. As compared with group 2 (placebo), pain scores were lower in group 1 (bupivacaine) in the first 2 postoperative days, and the difference was significant for the first 8 hours postoperatively (5.2 ± 0.4 versus 3.6 ± 0.4 , respectively; $p < 0.02$). During the first 3 postoperative days (Fig 2), only 9% of the patients in group 1 (bupivacaine) had a mean postoperative pain score of 5 or more as compared with 40% in group 2 (placebo) ($p < 0.05$) and 13% in group 3 (buprenorphine) (not significant). Similar amounts of supplemental buprenorphine were given in groups 1 and 3. However, the mean total dose of buprenorphine given throughout the 5 study days was significantly lower in groups 1 (1.95 ± 0.03 mg) and 2 (1.85 ± 0.03 mg) than in group 3 (4.8 ± 0.04 mg; $p < 0.001$).

All patients had severe reductions in vital capacity, forced expiratory volume in 1 second, and maximal inspiratory and expiratory pressures on day 1 with incomplete recovery on day 10 (Fig 3). There were no significant differences between the groups at any time in the absolute values of vital capacity, forced expiratory volume in 1 second, or maximal inspiratory and expiratory pressures

or in decreases in these parameters as compared with preoperative values. There were no correlations at any time between pain scores and any parameter of pulmonary function. There were no differences in heart rate, systolic and diastolic blood pressure, or temperature between the three groups throughout the study.

No complications developed related to the intercostal catheter or to administration of intercostal bupivacaine. Five respiratory complications (21%) occurred in group 2 (saline solution) (atelectasis in 3 patients, pneumopathy in 2 patients), as compared with none in group 1 (bupivacaine) ($p < 0.05$) and group 3 (buprenorphine) ($p < 0.05$).

Comment

This prospective, randomized study was designed to determine whether continuous intercostal infusion of 0.5% bupivacaine could provide good postoperative pain relief as compared with fixed-schedule or on-demand narcotics.

Analysis of self-assessed pain scores in our patients provided support for this hypothesis. In terms of postoperative pain relief, intercostal bupivacaine blockade was superior to on-demand intramuscular narcotics (group 2; saline solution) but similar to fixed-schedule intramuscular narcotics. However, the total amount of narcotics used was lower with intercostal bupivacaine than with fixed-schedule intramuscular narcotics.

The daily dose of bupivacaine given was 360 mg, which is approximately half the daily dose used by others for intermittent or continuous administration of intercostal bupivacaine [6-9]. With this dosage no evidence of bupivacaine toxicity was observed in our patients. However,

Fig 1. Each point represents an averaged self-assessed pain score and standard error of the mean for a given observation period in each of the three experimental groups. (Day 0 = first 8 hours after operation; * $p < 0.02$, intercostal bupivacaine compared with intercostal saline solution.)

Fig 2. Percentage of patients in each group with mean pain score of 5 or more for the first 3 postoperative days. (* $p < 0.05$, intercostal bupivacaine and fixed-schedule buprenorphine compared with intercostal saline solution.)

as previously reported [7, 9, 10, 11], intercostal infusion of bupivacaine failed to provide complete analgesic effect. Possible explanations include the need to anesthetize higher intercostal nerves or to increase the dosage of bupivacaine [8].

Of major clinical importance is the absence of pulmonary complications in the group given the continuous intercostal blockade as compared with the group given intramuscular on-demand narcotics alone. This difference could be related to some discomfort caused by the indwelling catheter itself in the placebo group or, more likely, to the ability of patients in the group given the continuous intercostal blockade to comply with physical therapy because of good pain relief.

Effects on ventilatory function of bupivacaine-induced pain relief are less conclusive because reductions in lung volumes were similar in all three groups. However, many factors are involved in the development of restrictive impairment after thoracotomy [1, 2], and consequently the relative contribution of pain is uncertain. The extent of the lung resection is one important contributory factor. It likely accounts for the difference between our findings and those of Sabanathan [8], Toledo-Pereyra [10], Kaplan [11], and their associates, who reported improvement of postoperative pulmonary dysfunction after intercostal blockade. In their studies, however, thoracotomy was performed for both pulmonary and nonpulmonary operations, whereas all our patients underwent lung resection, which may have counteracted the beneficial effect of pain relief on respiratory function. Another cause of postoperative lung restriction that may be unaffected by pain relief is dysfunction of inspiratory muscles [12]. However, although respiratory muscle dysfunction has been shown to be unaffected by analgesia after upper abdominal operations [13], the effect of pain relief on inspiratory muscles has not been investigated after thoracic operations. In our study, decreases in lung volume were associated with parallel alterations in maximal inspiratory pressures, which reflect the strength of inspiratory muscles. Maximal inspiratory pressures were not correlated with pain scores, so reductions in maximal inspiratory pressures were similar in all the three groups.

Fig 3. Absolute mean and standard error of the mean values of forced expiratory volume in 1 second (FEV₁), vital capacity (VC), and maximal static expiratory (PE_{max}) and inspiratory (PI_{max}) pressures in the three experimental groups over the study period. (PRE = preoperative values.)

We therefore suspect that pain relief-independent inspiratory muscle dysfunction may also account for our findings.

Continuous intercostal nerve blockade with bupivacaine through an indwelling catheter inserted during thoracotomy has several advantages over other methods of analgesia: (1) Intraoperative placement of the intercostal catheter reduces the risk of catheter malposition and pneumothorax associated with percutaneous insertion; malposition occurred in 3 of 52 patients in our early experience. (2) Although continuous intercostal bupivacaine appeared to have no benefit over fixed-schedule narcotics in pain relief, postoperative pulmonary complications, or pulmonary function, satisfactory analgesia was obtained with only a moderate amount of supplemental narcotics, thus minimizing the risk of narcotic-induced respiratory depression and cough reflex suppression. (3) The absence of sympathetic blockade, systemic hypotension, and respiratory depression are advantages of intercostal bupivacaine as compared with epidural bupivacaine. (4) Compared with the interpleural route, the intercostal route has been shown to provide comparable analgesia despite lower plasma bupivacaine levels [14]. Furthermore, in contrast to intercostal blockade, interpleural analgesia is not feasible after pneumonectomy. (5)

Finally, intercostal bupivacaine can be administered by the ward nursing staff, thus obviating the need for admission to high-dependency or intensive care units.

In conclusion, continuous intercostal blockade by bupivacaine is a safe, effective, easily administered form of analgesia after thoracotomy. This technique can be routinely used but is especially recommended for patients with impaired preoperative ventilatory function.

This work was supported by a grant from the Laboratoire Roger Bellon, Neuilly sur Seine, France.

REVIEW OF RECENT BOOKS

Tricuspid Atresia, Second Edition

Edited by P. Syamasundar Rao, MD

Mt. Kisco, NY, Futura, 1992

458 pp, illustrated, \$98.00

Reviewed by John H. Calhoun, MD

This monograph deals with tricuspid atresia in great detail. As such, it is not a book that every cardiovascular surgeon or cardiologist would need. However, it is a resource for those who do pediatric cardiac surgery and pediatric cardiology.

The text is divided into three sections. The first section, entitled "Background and the Basis," discusses in-depth historical features and classifications of the disease. Also, there is a complete chapter on demographic features of tricuspid atresia and an excellent review of the embryology. The conduction system is covered in an extensive chapter in a manner helpful to surgeons and cardiologists alike. Finally, classification is clarified by Dr Rao.

The second section is devoted to diagnosis. Because tricuspid atresia presents in a variety of manners, a clinical spectrum is developed in the first chapter of this section. Electrocardiographic features of the disease are reviewed in a separate chapter. The noninvasive evaluation of patients with tricuspid atresia is reviewed with attention to echocardiography, nuclear studies, and standard roentgenography. Included are chapters on exercise testing, cardiac catheterization, and angiography for tricuspid atresia. A chapter on left ventricular function is covered in

this portion of the text. The final chapter, "Natural History of Ventricular Septal Defects and Tricuspid Atresia," reviews this aspect of the disease and stresses the potential importance of the defect diagnostically.

The final section is devoted to the treatment and prognosis of patients with tricuspid atresia. A review of the treatment ranging from early pulmonary artery banding for initially overcirculated patients or shunt placement for undercirculated patients is made. Subsequent palliative operations including standard Glenn procedures, additional shunt operations, and bidirectional Glenn procedures are reviewed. Experimental work performed over the last 30 years on the physiology of the pulmonary circulation is reviewed in depth by Dr Sade. The Fontan operation is explored in detail, including its application in higher risk patients. A brief mention is made of the fenestration procedure and its possible role. An important set of chapters compile a vast amount of long-term follow-up on the Fontan procedure in patients with tricuspid atresia, including electrophysiologic, hemodynamic, and reference data toward sexuality and pregnancy in this subset of patients.

Dr Rao has compiled a wealth of information in a relatively short and readable text. This resource book is probably the most complete review of any congenital heart defect available. As such, it is recommended to all who treat patients with tricuspid atresia.

Homograft Aortic Root Replacement for Destructive Prosthetic Endocarditis

Harinder Singh Bedi, MCh, and Alan E. Farnsworth, FRCS(Ed)

Department of Cardiothoracic Surgery, St. Vincent's Hospital, Sydney, Australia

Prosthetic aortic valve endocarditis with extensive destruction of the aortic root, annular abscess formation, and left ventriculoaortic discontinuity was seen in 3 patients, with aorta to left atrial fistula formation in 2. Homograft aortic root replacement with use of the anterior mitral leaflet of the aortic root to repair the fistula

was used successfully in all 3 patients. Their case reports are discussed to highlight the use of the homograft aortic root in these complicated cases, and to report the occurrence of aorto-left atrial fistula in prosthetic valve endocarditis.

(*Ann Thorac Surg* 1993;55:386-8)

Prosthetic valve endocarditis is a highly lethal, though fortunately uncommon, complication of cardiac valve replacement. Increasing surgical expertise and the high mortality with medical management have led to a more aggressive surgical-medical approach to prosthetic valve endocarditis. At times, the infective process may be extensive and destructive, and simple debridement and valve replacement may not be sufficient. Often one or more previous corrective surgical procedures have been performed, which produce a successively greater distortion of normal anatomy. This is exemplified by the patient with destructive aortic prosthetic valve endocarditis with aortic root abscess. A number of techniques to treat such patients have been described [1-5]. We describe our experience with one of these techniques: homograft aortic root replacement in 3 patients with complicated aortic prosthetic valve endocarditis.

Case Reports

Patient 1

A 26-year-old female patient was referred to the Cardiothoracic Surgical Unit of St Vincent's Hospital, Sydney, with a malfunctioning prosthetic aortic valve. Six years earlier she was operated on for acute streptococcal native aortic valve and root endocarditis. At that time, a prominent abscess was found in the region of the aorto-mitral continuity with complete destruction of the non-coronary cusp of the aortic valve. After aortic valve excision and debridement of the abscess, the abscess cavity was closed off with a Dacron patch. A 21-mm Björk-Shiley aortic mechanical prosthesis was used to replace the aortic valve.

The patient was asymptomatic for 8 months, after which aortic regurgitation developed due to prosthetic and left ventricular outflow patch dehiscence. The patient was reoperated on at this stage with excision and replace-

ment of the prosthetic patch and valve. Subsequently she underwent four open cardiac surgical procedures for prosthetic valvular and left ventricular outflow tract dysfunction over the next 3 years. Details of the various operative procedures have been outlined in a previous case report [6], the last open cardiac operation being a repair of a dehiscenced prosthetic St. Jude valve and Dacron patch.

In March 1988, 6 years after the first operation, she was seen with persisting paravalvular aortic regurgitation and hemolytic anemia and was taken for operation. Cardiopulmonary bypass was instituted with femoral arterial and right atrial cannulation. The partially detached St. Jude valve and Dacron patch were excised. A homograft aortic root replacement with reimplantation of the coronary arteries was carried out using freshly prepared antibiotic-sterilized aortic root homograft harvested from the recipient heart of a transplant patient in the unit. The postoperative period was uneventful. An echocardiogram showed a normally functioning aortic valve and left ventricle.

Patient 2

A 37-year-old man was admitted to a peripheral hospital with a 2-day history of fever, malaise, vomiting, headache, and rigors. His blood culture was positive for *Staphylococcus aureus*, and an echocardiogram showed vegetations on the posterior aortic valve leaflet. He was put on a regimen of appropriate antibiotics, but his fever continued. An aortic regurgitation murmur developed, and his condition deteriorated.

He was referred on July 20, 1989. He was found to be in extremis, febrile, dyspneic, and anemic with hepatosplenomegaly, raised jugular venous pressure, and multiple skin lesions with the skin peeling off his hands and feet. His electrocardiogram revealed a first-degree heart block.

After his condition failed to stabilize on intense medical therapy, he was taken for emergency operation, where 500 mL of sanguineous fluid was found in the pericardium. There was intense inflammation around the aortic

Accepted for publication May 12, 1992.
